Modularly Metaprogrammable Type Structure

Abstract

We introduce Verse, a programming language specified, like many modern languages are, by a typed translation semantics targeting a common intermediate language (e.g. CIL bytecode, though for simplicity, we use a simply typed lambda calculus). In contrast to large such languages like Scala, the external language of Verse is remarkably small, building in only function types directly. In lieu of other type structure, Verse provides a metaprogramming mechanism that gives library providers the ability to modularly express type structure of their own design. For example, record types are not built in, but they can be expressed by defining a *tycon structure* that introduces a type constructor, `record`, together with record introduction and row projection operators. The logic governing the typechecking and translation of these operators is defined using a static metalanguage where types and translations are manipulated as values.

Verse performs translation validation to guarantee type safety and *conservativity*: that a broad class of metatheorems about such logic, including those establishing translation invariants, need only be established in a "closed world", i.e. as if the collection of tycon structures was finite. These are necessarily conserved in the "open world", i.e. when new tycon structure are introduced, with no new proof obligations. This critical modularity result relies on type abstraction to ensure that each tycon structure maintains *translation independence* with respect to all others.

1. Introduction

A key feature of the ML module system is that it supports type abstraction at interface boundaries [28]. This enables programming "in the large" by localizing reasoning about data representation invariants and making it possible to evolve these representations without breaking client programs. There is substantial agreement between dialects of ML about the value of this fundamental feature. Other languages are also increasingly converging on an ML-like design, e.g. Haskell [24] and Scala [2]. Verse, the language that we will introduce in this paper, does not buck this trend, providing a module system essentially identical to the Standard ML module system [28].

Where there are more substantial differences between languages is with regard to the semantics of the underlying core language, i.e. the language of types and expressions. Indeed, the language design community has produced hundreds of full-scale languages, toy dialects and minimal calculi that explore different points in the design space of core language constructs. For example:

- **General Purpose Constructs:** Many variations on products exist: n-ary tuples, labeled tuples, records (identified up to reordering), records with extension and update operators[1] [25], and records with width and depth coercions [9]. Disjunctive types also come in variants: standard datatypes, open datatypes [27, 30], polymorphic variants [25] and exception types [31]. Combinations occur as class-based object systems, of which there are a seemingly endless variety.
- **Specialized Constructs:** More specialized constructs are also commonly introduced in dialects, e.g. for distributed programming [32], concurrency [42], reactive programming [29], databases [34], units of measure [23], typechecking XML schemas [22], web programming [12] and string sanitation [18].
- l**Foreign Constructs:** A safe and natural foreign function interface (FFI) can be valuable for interacting with legacy or low-level device code. This requires enforcing the type system of the foreign language in the calling language. For example, MLj builds in a safe FFI to Java [5].

This *dialect-oriented* state of affairs is profoundly anti-modular. In other words, there is generally no good way to interface with a library written using a dialect different from one's own when a direct FFI is not available. There are, of course, bad ways to attempt this. For example, one can find a compiler for the foreign dialect that targets a language for which an FFI is available, e.g. JVM or CIL bytecode, and then program against the code it generates. But this bypasses the language semantics (i.e. the interface), exposing implementation details directly. Only the type system of the intermediate language, not of the dialect itself, constrains this action. If the compiler maintains any stronger translation invariants, there is no guarantee that they will be maintained. Moreover, if a different compiler is used, or the compiler evolves its choices regarding data representations, client code can break.

It is clear that the only scalable way to program "in the large" is to stick to a single programming language that provides strong modular reasoning principles. Once one accepts that dialects are better rhetorical vehicles than practical artifacts, there are two options. One, exemplified by languages like Scala and Ocaml, is to attempt to build in a large number of constructs into the core language *a priori*, and progressively add new ones as they emerge in backwards compatible revisions. Power is centralized around a small group of language designers. This results in a large core language, but because of a "long tail" effect, constructs that are situationally useful, or where there is disagreement, can still end up marginalized. Other constructs that are included but turn out to be flawed remain entrenched (and monopolize finite "syntactic resources", as we will discuss below).

Verse aims to explore the polar opposite end of this spectrum: a core language that builds in only minimal type structure *a priori*. Instead, the core language is organized around a metaprogramming mechanism that gives library providers the ability to introduce new type structure of their own design, within reasonable constraints.

[1] The Haskell wiki states that "extensible records are not implemented in GHC. The problem is that the record design space is large, and seems to lack local optima. [...] As a result, nothing much happens." [1]

The main challenge in decentralizing the semantics of a core language comes in maintaining strong metatheoretic properties. For example, if we simply conceived of the core language's semantics as being specified by a "bag of rules" and let library providers introduce new rules, one could easily define rules that violated type safety, interfered with invariants being maintained by rules defined in other libraries, or introduced non-determinism. There is also a question of how to allocate finite syntactic resources. For example, as the footnote above noted, the design space around record types is large. If we allow libraries to explore this design space, which library gets to determine the meaning of a form like `{label1: e1, label2: e2}`?

This paper is intended to introduce principled solutions to these problems. The key construct that the core language is organized around is called the *tycon structure*. A tycon structures defines a type constructor and the semantics of the operators associated with it using statically evaluated metafunctions. The language enforces an abstraction barrier around each tycon structure that ensures that they cannot interfere with one another, which preserves modular reasoning. Encouragingly, type abstraction is critical to this abstraction barrier, much like it is to the abstraction barrier between modules. A bidirectional type system is used to resolve ambiguities with regard to common forms, like the record introduction form shown above (following recent work on ambiguity-free syntax extensions in the Wyvern programming language [35]).

We will discuss labeled tuples with functional update, records and *regular strings* (based on a recent specification [18]) as examples of constructs that are, or would need to be, built in to comparable languages but that can be expressed as modular tycon structures in Verse. This mechanism is not all-encompassing – there are many compelling constructs that cannot be expressed in Verse today. We will discuss its limitations more specifically in Sec. 6. But this paper sets the "ground rules" of the game: we expect future versions of the language, and competing languages, to provide metatheoretic guarantees at least as strong as those we establish here, while being ever more expressive.

The remainder of the paper is organized as follows:

- In Sec. 2, we give a tutorial-style introduction to Verse.
- In Secs. 3-4, we give a formal account of tycon structures and the translation validation process with a typed lambda calculus, λ_{Verse}. The accompanying supplement contains more details.
- In Sec. 5, we summarize the key metatheoretic properties of the calculus introduced in Sec. 3.
- In Sec. 6, we compare tycon structures to other related work, and discuss present limitations and avenues for future work.

2. Verse by Example

From the perspective of an everyday programmer, Verse handles very much like other typed function programming languages. For example, let us build a (toy) academic conference management application in Verse, beginning with some type synonyms:

```
let type Title = rstr /.+/
let type Conf = rstr /([A-Z]+) (\d\d\d\d)/
let type Paper = record {
    title : Title,
    conf : Conf
}
```

Starting from the bottom up, `Paper` is a *record type* that specifies two rows. The first is labeled `title` and specifies type `Title`, and the second is labeled `conf` and specifies type `Conf`.

The types `Title` and `Conf` are *regular string types*, which behave as strings known statically to be in a regular language specified by a regular expression [18]. Here, `Title` specifies non-empty strings, and `Conf` specifies conference names in the standard format, i.e. a series of capital letters followed by a four-digit year. Parentheses indicate captured groups.

All types in Verse arise by applying a *type constructor* (*tycon*, for short) to a statically valued *type index*. Here, the tycon `rstr` is indexed by statically valued regular expressions, and `record` is indexed by statically valued finite mappings from labels to types. We are able to write the indices above using conventional concrete syntax not because this syntax is built in to Verse, but because Verse supports *type specific languages* (TSLs), a feature recently introduced in the Wyvern programming language that permits modular reasoning about syntax extensions [35]. For concision, we will not go into a detailed discussion about TSLs in this paper.

We can now define a function that generates papers as follows:

```
fun exmpl_paper(title : Title) -> Paper
  {title=title, conf="EXMPL 2015"}
```

and then call it and perform some further operations:

```
let paper = exmpl_paper "Collapsing The Multiverse"
let year = paper#conf#2
```

The value of `year` projects out the row labeled `conf` from the record `paper`, and then the substring corresponding to the second captured group, i.e. the year. Had we specified an incorrect row label, or an out-of-bounds captured group index, we would encounter a static type error. Note also that type annotations were not needed on these bindings, because Verse supports local type inference [37]. The type of `year` here is synthesized to be `rstr /\d\d\d\d/`.

If Verse were organized like a standard language and simply built in the type structure that we saw being used above – functions, records and regular strings – this would be only somewhat novel (regular strings are not widely available in languages like Ocaml and Scala). But neither records nor regular strings are built directly in to Verse. Instead, the core language of Verse is structured like the first stage of a type-directed compiler, e.g. the TIL compiler for Standard ML [46]. It consists of an *external language* (EL) defined by a type-directed translation to a much simpler *typed internal language* (IL). In other words, all external types and expressions (like those just defined) map, as they are being typechecked, to internal types and expression, respectively. Only the IL has a conventional dynamic semantics.

Only function types are built in to the EL. The Verse IL, for the purposes of this paper, builds in only functions, nullary and binary products, binary sums, recursive types, strings and numbers, i.e. it is reminiscent of a simple first-stage compiler IL. In practice, we would include a few other typical constructs, e.g. reference cells, contiguous arrays and concurrency primitives, but our design is largely independent of the details of the IL, so we omit discussion of these details.

Ultimately, the translation generated for the example above will be the following (assuming suitable helper functions, not shown):

```
let type Title = string
let type Conf = string
let type Paper = Title * (Conf * unit)

fun exmpl_paper(title : Title) -> Paper
  (title, ("EXMPL 2015", ()))

let paper = exmpl_paper "Collapsing the Multiverse"
let year = groupPrj 2 /([A-Z]+) (\d\d\d\d)/ (
  fst(snd(paper)))
```

External functions translate directly to internal functions. All other types and operations, however, delegate to *statically evaluated metafunctions* associated with *tycon structures*. Let us consider the `record` tycon structure in Figure 1.

The first line names the tycon structure and then ascribes a *tycon signature* to it, which specifies the "interface" associated with the

```
1  tycon structure record ~ tcsig {
2    indexed by LblTyMap
3    ana intro indexed by Lbl list
4    syn # indexed by Lbl
5  } = tcstruct {
6    translation = fn (tyidx : LblTyMap) -> ITy =>
7      fold tyidx `unit` (fn (lbl, ty) (rtr) =>
8        `trans(ty) * %rtr`)
9    ana intro = fn tyidx tmidx args =>
10     fold3 tyidx tmidx args `()` (
11       fn (lbl, ty) (rowlbl) (rowarg) (rtr) =>
12         let _ = lbleq lbl rowlbl
13         let rowtr = ana rowarg ty
14         `(%rowtr, %rtr)`)
15   syn # = fn tyidx tmidx args =>
16     let arg0 = arity0 args
17     let (ty, pos) = lookup tyidx tmidx
18     (ty, generate_prj pos arg0)
19 }
```

Figure 1. The tycon structure defining `record` types.

tycon structure. Here, line 2 states that the tycon is indexed by static values of *kind* `LblTyMap`. Kinds serve as the types of static values (discussed further in the next section). We assume that this kind has been defined previously and specifies kind-specific syntax as mentioned when we described the record type `Paper` above.

The next two lines in the tycon signature specify two *operator constructors* (or *opcons*) associated with the tycon. The first is the introductory opcon. It is used when one writes a record literal, as in the body of `exmpl_paper` above. The prefix **ana** means that it can only be used in an analytic position, i.e. when an expected type is known. This is to ensure that the common set of introductory forms available in the language, like the record and string introductory forms shown being used in the examples above, can be unambiguously leveraged at many types. The semantics delegates to the tycon of the type that an expression of such a form is being analyzed against, as we will discuss in great detail below. The clause **indexed by** `Lbl list` specifies that only introductory forms from which a list of statically valued labels can be derived are valid for introducing records. In this case, this means that only the record literal form is valid, but not the string literal form.

The second opcon is written `#`, and is used with the generalized projection form in the Verse syntax. This is the syntax that is used in the example above to project the row `conf` from `paper`. The prefix **syn** means that it synthesizes a type. The clause **indexed by** `Lbl` indicates that a statically valued label, i.e. the name of the row being requested, must be provided to the opcon. The language delegates to the tycon of the type of the expression serving as the target of the projection. Again, we will discuss this in great detail below.

The remainder of the listing gives the implementation of the tycon structure. The first component computes a *type translation* for record types as a metafunction of the type index. Here, we choose to translate record types to nested binary product types by folding over the type index, with the base case being the nullary product type, `unit`. Note that we are using quasiquotation syntax here to compute the type translation (another mode of use of TSLs). The form `trans(ty)` refers *abstractly* to the translation of another type. As we will see, the key to modular reasoning about tycon structures is *translation independence*: that no other tycon structure can rely on the choice made here. The definition of records here could just as well use a different row ordering in its representation, or a different internal data structure entirely (e.g. a list instead of nested pairs). Here, the representation of the record type `paper` will be `trans(Title) * (trans(Conf) * unit)`. We could optimize the trailing unit away, but we leave it for simplicity and to again emphasize that this is merely an implementation detail.

internal types
$\tau \quad ::= \quad \alpha \mid \tau \rightharpoonup \tau \mid \forall(\alpha.\tau) \mid \mu(\alpha.\tau) \mid 1 \mid \tau \times \tau \mid \tau + \tau$
internal terms
$\iota \quad ::= \quad x \mid \lambda x{:}\tau.\iota \mid \iota(\iota) \mid \mathsf{fix}[\tau](x.\iota) \mid \Lambda(\alpha.\iota) \mid \iota[\tau]$
$\quad\quad \mid \quad \mathsf{fold}[t.\tau](\iota) \mid \mathsf{unfold}(\iota) \mid () \mid (\iota,\iota) \mid \mathsf{fst}(\iota) \mid \mathsf{snd}(\iota)$
$\quad\quad \mid \quad \mathsf{inl}[\tau](\iota) \mid \mathsf{inr}[\tau](\iota) \mid \mathsf{case}(\iota; x.\iota; x.\iota)$
internal typing contexts $\Gamma ::= \emptyset \mid \Gamma, x : \tau$
internal type formation contexts $\Delta ::= \emptyset \mid \Delta, \alpha$

Figure 2. Syntax of our internal language (IL). Metavariable x ranges over term variables and α (or t) over type variables.

The remainder of the tycon structure determines the typechecking and translation logic governing the introductory and projection operators mentioned, and shown being used, above. We will return to the details of what is happening in subsequent sections. The main thing to notice for now is that types and translations are being statically computed. For example, one should be able to make out that nested pairs are being constructed in the intro opcon definition, and that we are projecting out the appropriate component based on the label provided to the projection opcon. Because projection is a synthetic opcon, it returns a pair of an (external) type and translation, whereas introduction returns only a translation. On line 13, it requests type analysis of an argument to the operation (i.e. a row value) against a corresponding type, showing how the typechecker is exposed to the metalogic.

To summarize: the semantics delegated control over 1) translation of the record type `Paper`; 2) translation of the record literal in `exmpl_paper` and 3) type synthesis and translation of the projection operator used to compute `paper#conf` to the `record` tycon structure, rather than specifying this logic *a priori*. Similarly, though not shown here, the `rstr` tycon was delegated control over 1) translation of the types `Title` and `Conf`; 2) translation of the string literals in the examples and 3) type synthesis and translation of the group projection operator. The language guaranteed that the choice of representation made by each tycon is known only to its opcons, so metatheoretic reasoning about whether, for example, `rstr` correctly constrains its translation by the regular language provided as the type index is entirely local.

3. Overview of λ_{Verse}

Let us now make the intuitions in the previous section completely precise, by specifying a core calculus, λ_{Verse}. We cover the most important rules in the paper, but a significantly more detailed treatment is provided in the accompanying supplement.

Internal Language At the heart of our semantics is a typed internal language supporting type abstraction (i.e. universal quantification over types) [40]. We use $\mathcal{L}\{\rightharpoonup \forall\, \mu\, 1 \times +\}$, Figure 2, as representative of a typical intermediate language for a typed language. We assume an internal statics specified by judgements for type assignment $\Delta\ \Gamma \vdash \iota : \tau^{-}$, type formation $\Delta \vdash \tau$ and typing context formation $\Delta \vdash \Gamma$, and an internal dynamics specified as a structural operational semantics with a stepping judgement $\iota \mapsto \iota^{-}$ and a value judgement ι `val`.[2] Both the static and dynamic semantics of the IL can be found in any standard textbook covering typed lambda calculi (e.g. [20] or [36]), so we assume familiarity.

External Language Programs "execute" as internal terms, but programmers interface with λ_{Verse} by writing *external terms*, e. The abstract syntax of external terms is shown in Figure 3 and we introduce various concrete desugarings as we go on. The semantics are specified as a *bidirectionally typed translation semantics*, i.e. the key judgements have the following form, pronounced "Under typing context Υ and tycon context Φ, e (synthesizes / analyzes

[2] Our specifications are intended to be algorithmic: we indicate "outputs" when introducing judgement forms by *mode annotations*, $^{-}$.

external terms

$$\begin{array}{lcl} e & ::= & x \mid \lambda x.e \mid \lambda x{:}\sigma.e \mid e(e) \mid \mathsf{fix}(x.e) \mid e : \sigma \\ & \mid & \mathsf{intro}[\sigma](\overline{e}) \mid \mathsf{targop}[\mathbf{op};\sigma](e;\overline{e}) \end{array}$$

argument lists $\overline{e} ::= \cdot \mid \overline{e}; e$

external typing contexts $\Upsilon ::= \emptyset \mid \Upsilon, x : \sigma$

Figure 3. Abstract syntax of the external language (EL).

against) type σ and has translation ι":

$$\Upsilon \vdash_\Phi e \Rightarrow \sigma^- \rightsquigarrow \iota^- \quad \text{and} \quad \Upsilon \vdash_\Phi e \Leftarrow \sigma \rightsquigarrow \iota^-$$

We distinguish situations where the type is an "output" from those where it must be provided as an "'input" using such a bidirectional approach, also known as *local type inference* [37], for two reasons. The first is to justify the practicality of our approach: local type inference is increasingly being used in modern languages (e.g. Scala [33]) because it eliminates the need for type annotations in many places and provides high quality error messages. Secondly, it will give us a clean way to reuse the abstract introductory form, $\mathsf{intro}[\sigma](\overline{e})$, and its associated desugarings, at many types.

For example, consider the following types:

$$\begin{array}{lcl} \sigma_{\text{title}} & := & \text{RSTR}\langle /.+/ \rangle \\ \sigma_{\text{conf}} & := & \text{RSTR}\langle /\texttt{[A-Z]+ \textbackslash d\textbackslash d\textbackslash d\textbackslash d}/ \rangle \\ \sigma_{\text{paper}} & := & \text{LPROD}\langle \{\texttt{title} : \sigma_{\text{title}}, \texttt{conf} : \sigma_{\text{conf}}\} \rangle \end{array}$$

The *regular string types* σ_{title} and σ_{conf} classify values that behave as strings known to be in a specified regular language [18], i.e. σ_{title} classifies non-empty strings and σ_{conf} classifies strings having the format of a typical conference name. The *labeled product type* σ_{paper} then describes a conference paper by defining two *rows*, each having one of the regular string types just described. Regular string types are defined by tycon context Φ_{rstr} and labeled products by Φ_{lprod}, both introduced in Sec. 3.

We next define a function, e_{ex}, that takes a paper title and produces a paper in a conference named `"EXMPL 2015"`:

$$\begin{array}{lcl} e_{\text{ex}} & := & \lambda \mathit{title}{:}\sigma_{\text{title}}.(e_{\text{paper}} : \sigma_{\text{paper}}) \\ e_{\text{paper}} & := & \{\texttt{title}{=}\mathit{title}, \texttt{conf}{=}\texttt{"EXMPL 2015"}\} \end{array}$$

We will detail the syntax and semantics in Sec. 4. To briefly summarize: because of the type ascription σ_{paper} in e_{ex}, semantic control over e_{paper} will be delegated to the *intro opcon definition* of LPROD. It will decide to analyze the the row value of `title` against σ_{title} and the row value of `conf`, a string literal, against σ_{conf}, causing control to pass similarly to RSTR. Satisfied that the term is well-typed, these will generate translations. Thus, we will be able to derive:

$$\emptyset \vdash_{\Phi_{\text{rstr}}\Phi_{\text{lprod}}} e_{\text{ex}} \Rightarrow (\sigma_{\text{title}} \rightharpoonup \sigma_{\text{paper}}) \rightsquigarrow \iota_{\text{ex}}$$

where $\iota_{\text{ex}} := \lambda \mathit{title}{:}\mathsf{str}.(\mathit{title}, (\texttt{"EXMPL 2015"}_{\text{IL}}, ()))$. Note that labels need not appear, and $\texttt{"EXMPL 2015"}_{\text{IL}}$ is an internal string (of internal type `str`, defined suitably). The trailing unit value arises only because it simplifies our exposition. The type annotation on the internal function could be determined because types also have translations, specified by the *type translation judgement* $\vdash_\Phi \sigma\ \texttt{type} \rightsquigarrow \tau^-$, read "$\sigma$ is a type under Φ with translation τ". For example, σ_{title} and σ_{conf} have type translations `str` and σ_{paper} in turn has $\mathsf{str} \times (\mathsf{str} \times 1)$. Selectively holding type translations abstract will be the key to modular metatheoretic reasoning. For example, LPROD cannot claim that a row has a regular string type but produce a translation inconsistent with this claim: the translation $(\texttt{""}_{\text{IL}}, (\texttt{"EXMPL"}_{\text{IL}}, ()))$ is invalid for a term of type σ_{paper}, despite being of internal type $\mathsf{str} \times (\mathsf{str} \times 1)$. In fact, it will be checked against $\alpha_1 \times (\alpha_2 \times 1)$ (Sec. 4.3).

Static Language As suggested above, the main novelty of λ_{Verse} is that the types and term and type translations do not arise from a fixed specification. Rather, they are *statically computed* by tycon definitions using a *static language* (SL). The SL is itself a typed

kinds

$$\begin{array}{lcl} \kappa & ::= & \kappa \to \kappa \mid \boldsymbol{\alpha} \mid \forall(\boldsymbol{\alpha}.\kappa) \mid \boldsymbol{k} \mid \mu_{\text{ind}}(\boldsymbol{k}.\kappa) \mid 1 \mid \kappa \times \kappa \mid \kappa + \kappa \\ & \mid & \mathsf{Ty} \mid \mathsf{ITy} \mid \mathsf{ITm} \end{array}$$

static terms

lambda calculus where *kinds*, κ, serve as the "types" of *static terms*, σ. Its syntax is shown in Figure 4. The portion of the SL covered by the first row of kinds and static terms, some of which are elided, forms a standard functional language consisting of total functions, polymorphic and inductive kinds, and products and sums [20]. It can be seen as a total subset of ML.

Only three new kinds are needed for the SL to serve its role: 1) Ty, classifying types (Sec. 3); 2) ITy, classifying *quoted translational internal types*, used to compute type translations in Sec. 3.4; and (3) ITm, classifying *quoted translational internal terms*, used to compute term translations in Sec. 4.1. The forms $\mathsf{ana}[n](\sigma)$ and $\mathsf{syn}[n]$ will allow tycon definitions to request analysis or synthesis of operator arguments, linking the SL with the EL in Sec. 4.2.

The kinding judgement takes the form $\boldsymbol{\Delta}\ \boldsymbol{\Gamma} \vdash^n_\Phi \sigma :: \kappa^-$, where $\boldsymbol{\Delta}$ and $\boldsymbol{\Gamma}$ are analagous to Δ and Γ and analagous judgements $\boldsymbol{\Delta} \vdash \kappa$ and $\boldsymbol{\Delta} \vdash \boldsymbol{\Gamma}$ are defined. The natural number n is simply a bound used to prevent "out of bounds" references to arguments. The computational behavior of static terms (i.e. the *static dynamics*) is defined by a stepping judgement $\sigma \mapsto_{\mathcal{A}} \sigma^-$, a value judgement $\sigma\ \mathtt{val}_{\mathcal{A}}$ and an *error raised* judgement $\sigma\ \mathtt{err}_{\mathcal{A}}$. $\mathcal{A}$ ranges over *argument environments*, which we return to in Sec. 4.2. The multi-step judgement $\sigma \mapsto^*_{\mathcal{A}} \sigma^-$ is the reflexive, transitive closure of the stepping judgement and the normalization judgement $\sigma \Downarrow_{\mathcal{A}} \sigma'$ is derivable iff $\sigma \mapsto^*_{\mathcal{A}} \sigma'$ and $\sigma'\ \mathtt{val}_{\mathcal{A}}$.

Types Types are static values of kind Ty, i.e. we write $\sigma\ \mathtt{type}_\Phi$ iff $\sigma\ \mathtt{val}_{\mathcal{A}}$ and $\emptyset\ \emptyset \vdash^n_\Phi \sigma :: \mathsf{Ty}$. All types are of the form $c\langle\sigma\rangle$, where c is a *tycon* and σ is the *type index*. Three kinding rules govern this form, shown in Figure 5, one for each of the three forms for tycons given in Figure 6. The dynamics are simple and tycon-independent: the index is eagerly normalized and errors propagate (see supplement for the complete rules, lemmas and proofs from this paper).

Function Types In our example, we assumed a desugaring from $\sigma_1 \rightharpoonup \sigma_2$ to $\rightharpoonup\langle(\sigma_1, \sigma_2)\rangle$. The rule (k-ty-parr) specifies that the type index of partial function types must be a pair of types. We thus say that $\rightharpoonup$ has *index kind* $\mathsf{Ty} \times \mathsf{Ty}$.

Extension Types For types constructed by an *extension tycon*, written TC, rule (k-ty-ext) checks for a *tycon definition* for TC in the

(k-ty-parr)
$$\frac{\Delta\ \Gamma \vdash^n_\Phi \sigma :: \mathsf{Ty} \times \mathsf{Ty}}{\Delta\ \Gamma \vdash^n_\Phi \rightharpoonup\langle\sigma\rangle :: \mathsf{Ty}}$$

$\quad \cdots\} \sim \psi_{\mathrm{lprod}}$

Figure 7. Example tycon signatures and definitions.

tycon context, Φ. The syntax of tycon contexts is shown in Figure 6 and our main examples are in Figure 7. For now, the only relevant detail is that each tycon defines a *tycon signature*, ψ, which in turn defines the index kind used in the second premise of (k-ty-ext).

Types constructed by RSTR, e.g. σ_{title} and σ_{conf}, specify regular expressions as their indices. The tycon signature of RSTR, ψ_{rstr} in Figure 7, thus specifies index kind Rx, which classifies static regular expression patterns (defined as an inductive sum kind in the usual way). We wrote the type indices in our example assuming a standard concrete syntax. Recent work has shown how to define such type-specific, or here kind-specific, syntax composably [35].

Under the composed context $\Phi_{\mathrm{rstr}}\Phi_{\mathrm{lprod}}$, we defined the labeled product type σ_{paper}. The index kind of LPROD, given by ψ_{lprod} in Figure 7, is $\mathsf{List}[\mathsf{Lbl} \times \mathsf{Ty}]$, where list kinds are defined in the usual way, and Lbl classifies static representations of row labels, and we again used kind-specific syntax to approximate a conventional syntax for row specifications.

Other Types Rule (k-ty-other) governs types constructed by a tycon of the form $\mathsf{other}[m;\kappa]$. These will serve only as technical devices to stand in for tycons other than those in a given tycon context in Theorem 5. The natural number m serves to ensure there are arbitrarily many of these tycons. The index pairs any value of *equality kind* κ, discussed in Sec. 3.3, with a value of kind ITy, discussed in Sec. 3.4.

3.1 Type Case Analysis

Types might be thought of as arising from a distinguished "open datatype" [27] defined by the tycon context. Consistent with this view, a type σ can be case analyzed using $\mathsf{tycase}[c](\sigma; \boldsymbol{x}.\sigma_1; \sigma_2)$. If the value of σ is constructed by c, its type index is bound to $\boldsymbol{x}$ and branch σ_1 is taken. For totality, a default branch, σ_2, must be provided. For example, the kinding rule for extension tycons is:

(k-tycase-ext)
$$\frac{\Delta\ \Gamma \vdash^n_\Phi \sigma :: \mathsf{Ty} \qquad \mathsf{tycon}\ \mathrm{TC}\ \{\theta\} \sim \mathsf{tcsig}[\kappa_{\mathrm{tyidx}}]\ \{\chi\} \in \Phi \qquad \Delta\ \Gamma, \boldsymbol{x} :: \kappa_{\mathrm{tyidx}} \vdash^n_\Phi \sigma_1 :: \kappa \qquad \Delta\ \Gamma \vdash^n_\Phi \sigma_2 :: \kappa}{\Delta\ \Gamma \vdash^n_\Phi \mathsf{tycase}[\mathrm{TC}](\sigma; \boldsymbol{x}.\sigma_1; \sigma_2) :: \kappa}$$

We will see an example of its use in an opcon definition in Sec. 4.4. The rule for $c{=}\rightharpoonup$ is analagous, but, importantly, no rule for $c{=}\mathsf{other}[m;\kappa]$ is defined (these types always take the default branch and their indices cannot be examined).

3.2 Tycon Contexts

The tycon context well-definedness judgement, $\vdash\ \Phi$ is given in Figure 8 (omitting the trivial rule for $\Phi = \cdot$).

3.3 Type Equivalence

The first of the three checks in (tcc-ext), and the check in (k-ty-other), simplifies type equivalence: type index kinds must be *equality kinds*, i.e. those for which semantically equivalent values

(tcc-ext)
$$\frac{\vdash \Phi \qquad \emptyset \vdash \kappa_{\mathrm{tyidx}}\ \mathsf{eq} \qquad \emptyset\ \emptyset \vdash^0_\Phi \sigma_{\mathrm{schema}} :: \kappa_{\mathrm{tyidx}} \to \mathsf{ITy} \qquad \vdash_{\Phi, \mathsf{tycon}\ \mathrm{TC}\ \{\mathsf{trans}=\sigma_{\mathrm{schema}}\ \mathsf{in}\ \omega\} \sim \mathsf{tcsig}[\kappa_{\mathrm{tyidx}}]\ \{\chi\}} \omega \sim \mathsf{tcsig}[\kappa_{\mathrm{tyidx}}]\ \{\chi\}}{\vdash \Phi, \mathsf{tycon}\ \mathrm{TC}\ \{\mathsf{trans} = \sigma_{\mathrm{schema}}\ \mathsf{in}\ \omega\} \sim \mathsf{tcsig}[\kappa_{\mathrm{tyidx}}]\ \{\chi\}}$$

Figure 8. Tycon context well-definedness.

are syntactically equal. Equality kinds are defined by the judgement $\Delta \vdash \kappa\ \mathsf{eq}$ (see supplement) and are exactly analagous to equality types as in Standard ML [31]. Arrow kinds are not equality kinds.

3.4 Type Translations

Recall that a type, σ, defines a translation, τ. Extension tycons compute translations for the types they construct as a function of each type's index by specifying a *translation schema* in the tycon structure, θ. The translation schema must have kind $\kappa_{\mathrm{tyidx}} \to \mathsf{ITy}$, checked by the third premise of (tcc-ext). Terms of kind ITy are introduced by a *quotation form*, $\blacktriangleright(\hat{\tau})$, where $\hat{\tau}$ is a *translational internal type*. Each form of internal type, τ, has a corresponding form of translational internal type. For example, regular string types have type translations abbreviated $\hat{\mathsf{str}}$. Abbreviating the corresponding translational internal type $\hat{\mathsf{str}}$, we define the translation schema of RSTR as $\sigma_{\mathrm{rstr/trans}} := \lambda\boldsymbol{tyidx}{::}\mathsf{Rx}.\blacktriangleright(\hat{\mathsf{str}})$.

The syntax for $\hat{\tau}$ also includes an "unquote" form, $\blacktriangleleft(\sigma)$, so that they can be constructed compositionally, as well as a form, $\mathsf{trans}(\sigma)$, that refers to another type's translation. These have the following simple kinding rules:

(k-ity-unquote)
$$\frac{\Delta\ \Gamma \vdash^n_\Phi \sigma :: \mathsf{ITy}}{\Delta\ \Gamma \vdash^n_\Phi \blacktriangleright(\blacktriangleleft(\sigma)) :: \mathsf{ITy}}$$

(k-ity-trans)
$$\frac{\Delta\ \Gamma \vdash^n_\Phi \sigma :: \mathsf{Ty}}{\Delta\ \Gamma \vdash^n_\Phi \blacktriangleright(\mathsf{trans}(\sigma)) :: \mathsf{ITy}}$$

The semantics for the shared forms propagates the quotation marker recursively to ensure these are reached, e.g.

(k-ity-prod)
$$\frac{\Delta\ \Gamma \vdash^n_\Phi \blacktriangleright(\hat{\tau}_1) :: \mathsf{ITy} \qquad \Delta\ \Gamma \vdash^n_\Phi \blacktriangleright(\hat{\tau}_2) :: \mathsf{ITy}}{\Delta\ \Gamma \vdash^n_\Phi \blacktriangleright(\hat{\tau}_1 \times \hat{\tau}_2) :: \mathsf{ITy}}$$

These are needed in the translation schema for LPROD, which generates nested binary product types by folding over the type index and referring to the translations of the types therein. We assume the standard ***fold*** function in defining:

$$\sigma_{\mathrm{lprod/trans}} := \lambda\boldsymbol{tyidx}{::}\mathsf{List}[\mathsf{Lbl} \times \mathsf{Ty}].\boldsymbol{fold}\ \boldsymbol{tyidx}\ \blacktriangleright(1)\ (\lambda\boldsymbol{h}{:}\mathsf{Lbl} \times \mathsf{Ty}.\lambda\boldsymbol{r}{:}\mathsf{ITy}.\blacktriangleright(\mathsf{trans}(\mathsf{snd}(\boldsymbol{h})) \times \blacktriangleleft(\boldsymbol{r}))$$

Applying this translation schema to the index of σ_{paper}, for example, produces the value $\sigma_{\mathrm{paper/trans}} := \blacktriangleright(\hat{\tau}_{\mathrm{paper/trans}})$ where $\hat{\tau}_{\mathrm{paper/trans}} := \mathsf{trans}(\sigma_{\mathrm{title}}) \times (\mathsf{trans}(\sigma_{\mathrm{conf}}) \times 1)$. Note that references to translations of types are retained in values of kind ITy, while unquote forms are eliminated (see supplement for the full semantics of quotations).

3.4.1 Selective Type Translation Abstraction

References to type translations are maintained in values like this to allow us to selectively hold them abstract. This can be thought of as analagous to the process in ML by which the true identity of an abstract type in a module is held abstract outside the module until after typechecking. The judgement $\hat{\tau} \parallel \mathcal{D} \twoheadrightarrow^c_\Phi \tau^- \parallel \mathcal{D}^-$ relates a normalized translational internal type $\hat{\tau}$ to an internal type τ, called a *selectively abstracted type translation* because references to translations of types *constructed by a tycon other than the delegated tycon*, c, are replaced by a corresponding type

variable, α. For example, $\hat{\tau}_{\text{paper/trans}} \parallel \emptyset \hookrightarrow^{\text{LPROD}}_{\Phi_{\text{rstr}}\Phi_{\text{lprod}}} \tau_{\text{paper/abs}} \parallel \mathcal{D}_{\text{paper/abs}}$ where $\tau_{\text{paper/abs}} := \alpha_1 \times (\alpha_2 \times 1)$.

The *type translation store* $\mathcal{D} ::= \emptyset \mid \mathcal{D}, \sigma \leftrightarrow \tau/\alpha$ maintains the correspondence between types, their actual translations and the distinct type variables appearing in their place, e.g. $\mathcal{D}_{\text{paper/abs}} := \sigma_{\text{title}} \leftrightarrow \mathsf{str}/\alpha_1, \sigma_{\text{conf}} \leftrightarrow \mathsf{str}/\alpha_2$. The judgement $\mathcal{D} \rightsquigarrow \delta^- : \Delta^-$ constructs the n-ary *type substitution*, $\delta ::= \emptyset \mid \delta, \tau/\alpha$, and corresponding internal type formation context, Δ, implied by the type translation store $\mathcal{D}$. For example, $\mathcal{D}_{\text{paper/abs}} \rightsquigarrow \delta_{\text{paper/abs}} : \Delta_{\text{paper/abs}}$ where $\delta_{\text{paper/abs}} := \mathsf{str}/\alpha_1, \mathsf{str}/\alpha_2$ and $\Delta_{\text{paper/abs}} := \alpha_1, \alpha_2$.

We can apply type substitutions to internal types, terms and typing contexts, written $[\delta]\tau$, $[\delta]\iota$ and $[\delta]\Gamma$, respectively. For example, $[\delta_{\text{paper/abs}}]\tau_{\text{paper/abs}}$ is $\tau_{\text{paper}} := \mathsf{str} \times (\mathsf{str} \times 1)$, i.e. the actual type translation of σ_{paper}. Indeed, we can now define the type translation judgement, $\vdash_\Phi \sigma\ \mathtt{type} \rightsquigarrow \tau$, mentioned in Sec. 3. We simply determine any selectively abstracted translation, then apply the implied substitution:

(ty-trans)
$$\frac{\sigma\ \mathtt{type}_\Phi \qquad \mathsf{trans}(\sigma) \parallel \emptyset \hookrightarrow^{c}_{\Phi} \tau \parallel \mathcal{D} \qquad \mathcal{D} \rightsquigarrow \delta : \Delta}{\vdash_\Phi \sigma\ \mathtt{type} \rightsquigarrow [\delta]\tau}$$

The rules for the selective type translation abstraction judgement recurse generically over shared forms in $\hat{\tau}$. Only sub-terms of form $\mathsf{trans}(\sigma)$ are interesting. The translation of an extension type is determined by calling the translation schema and validating that the type translation it generates is closed except for type variables tracked by $\mathcal{D}'$. If constructed by the delegated tycon, it is not held abstract:

(abs-ext-delegated)
$$\frac{\begin{array}{c}\mathsf{tycon}\ \text{TC}\ \{\mathsf{trans} = \sigma_{\text{schema}}\ \mathsf{in}\ \omega\} \sim \psi \in \Phi \\ \sigma_{\text{schema}}(\sigma_{\text{tyidx}}) \Downarrow_{\cdot;\emptyset;\Phi} \blacktriangleright(\hat{\tau}) \\ \hat{\tau} \parallel \mathcal{D} \hookrightarrow^{\text{TC}}_{\Phi} \tau \parallel \mathcal{D}' \qquad \mathcal{D}' \rightsquigarrow \delta : \Delta \qquad \Delta \vdash \tau\end{array}}{\mathsf{trans}(\text{TC}\langle\sigma_{\text{tyidx}}\rangle) \parallel \mathcal{D} \hookrightarrow^{\text{TC}}_{\Phi} \tau \parallel \mathcal{D}'}$$

Otherwise, it is held abstract via a fresh type variable added to the store (the supplement gives rule (abs-ty-stored) for retrieving it if already there):

(abs-ext-not-delegated-new)
$$\frac{\begin{array}{c}c \neq \text{TC} \\ \text{TC}\langle\sigma_{\text{tyidx}}\rangle \notin \mathrm{dom}(\mathcal{D}) \qquad \mathsf{tycon}\ \text{TC}\ \{\mathsf{trans} = \sigma_{\text{schema}}\ \mathsf{in}\ \omega\} \sim \psi \in \Phi \\ \sigma_{\text{schema}}(\sigma_{\text{tyidx}}) \Downarrow_{\cdot;\emptyset;\Phi} \blacktriangleright(\hat{\tau}) \qquad \hat{\tau} \parallel \mathcal{D} \hookrightarrow^{c}_{\Phi} \tau \parallel \mathcal{D}' \\ \mathcal{D}' \rightsquigarrow \delta : \Delta \qquad \Delta \vdash \tau \qquad (\alpha\ \text{fresh})\end{array}}{\mathsf{trans}(\text{TC}\langle\sigma_{\text{tyidx}}\rangle) \parallel \mathcal{D} \hookrightarrow^{c}_{\Phi} \alpha \parallel \mathcal{D}', \text{TC}\langle\sigma_{\text{tyidx}}\rangle \leftrightarrow [\delta]\tau/\alpha}$$

The translations of "other" types are given directly in their indices (in Sec. 5, we will replace some extension types with other types, and this is how we preserve their translations):

(abs-other-delegated)
$$\frac{\hat{\tau} \parallel \mathcal{D} \hookrightarrow^{\mathsf{other}[m;\kappa]}_{\Phi} \tau \parallel \mathcal{D}' \qquad \mathcal{D}' \rightsquigarrow \delta : \Delta \qquad \Delta \vdash \tau}{\mathsf{trans}(\mathsf{other}[m;\kappa]\langle(\sigma, \blacktriangleright(\hat{\tau}))\rangle) \parallel \mathcal{D} \hookrightarrow^{\mathsf{other}[m;\kappa]}_{\Phi} \tau \parallel \mathcal{D}'}$$

Rule (abs-other-not-delegated-new) is analagous to (abs-ext-not-delegated-new), and is shown in the supplement.

The translations of function types are not held abstract, so that lambdas, which are built in, can be the sole binding construct in the EL:

(abs-parr)
$$\frac{\mathsf{trans}(\sigma_1) \parallel \mathcal{D} \hookrightarrow^{c}_{\Phi} \tau_1 \parallel \mathcal{D}' \qquad \mathsf{trans}(\sigma_2) \parallel \mathcal{D}' \hookrightarrow^{c}_{\Phi} \tau_2 \parallel \mathcal{D}''}{\mathsf{trans}(\rightharpoonup\langle(\sigma_1, \sigma_2)\rangle) \parallel \mathcal{D} \hookrightarrow^{c}_{\Phi} \tau_1 \rightharpoonup \tau_2 \parallel \mathcal{D}''}$$

4. External Terms

Now that we have established how types are constructed and how type translations are computed, we are ready to give the semantics for external terms, shown in Figure 9.

Because we are defining a bidirectional type system, the rule (subsume) is needed to allow synthetic terms to be analyzed against an equivalent type. Per Sec. 3.3, equivalent types must be syntactically identical at normal form, and we consider analysis only if $\sigma\ \mathtt{type}_\Phi$, so the rule is straightforward. To use an analytic term in a synthetic position, the programmer must provide a type ascription, written $e : \sigma$. The ascription is kind checked and normalized to a type before being used for analysis by rule (ascribe).

Rules (syn-var) states that variables synthesize types, as is standard. Functions operate in the standard manner given our definitions of types and type translations (used to generate annotations in the IL). We use Plotkin's fixpoint operator for general recursion (cf. [20]), and define it only analytically with rule (anafix). We also define an analytic form of lambda without a type ascription to emphasize that bidirectional typing allows you to omit type ascriptions in analytic positions.

4.1 Generalized Intro Operations

The meaning of the *generalized intro operation*, written $\mathsf{intro}[\sigma_{\text{tmidx}}](\overline{e})$, is determined by the tycon of the type it is being analyzed against as a function of the type's index, the *term index*, σ_{tmidx}, and the *argument list*, $\overline{e}$.

Before discussing rules (ana-intro) and (ana-intro-other), we note that we can recover a variety of standard concrete introductory forms by desugaring. For example, the string literal form, `"s"`, desugars to $\mathsf{intro}[\texttt{"s"}_{\text{SL}}](\cdot)$, i.e. the term index is the corresponding static value of kind Str and there are no arguments. Similarly, we define a generalized labeled collection form, $\{\mathtt{lbl}_1 = e_1, \ldots, \mathtt{lbl}_n = e_n\}$, that desugars to $\mathsf{intro}[\mathtt{lbl}_1, \ldots, \mathtt{lbl}_n](e_1; \ldots; e_n)$, i.e. a static list constructed from the row labels is the term index and the corresponding row values are the arguments. Additional desugarings are discussed in the supplement. The literal form in e_{paper}, from Sec. 3, for example, desugars to $e_{\text{paper}} := \mathsf{intro}[\mathtt{[title, conf]}](\mathit{title}; \mathsf{intro}[\texttt{"EXMPL 2015"}_{\text{SL}}](\cdot))$.

Let us now derive the typing judgement in Sec. 3. We first apply (syn-lam), which will ask $(e_{\text{paper}} : \sigma_{\text{paper}})$ to synthesize a type in the typing context $\Upsilon_{\text{ex}} = \mathit{title} : \sigma_{\text{title}}$. Then (ascribe) will analyze e_{paper} against σ_{paper} via (ana-intro).

The first premise of (ana-intro) simply finds the tycon definition for the tycon of the type provided for analysis, in this case LPROD. The second premise extracts the *intro term index kind*, κ_{tmidx}, from the *opcon signature*, χ, it specifies. This is simply the kind of term index expected by the tycon, e.g. in Figure 7, LPROD specifies List[Lbl], so that it can use the labeled collection form, while RSTR specifies Str, so that it can use the string literal form. The third premise checks the provided term index against this kind.

The fourth premise extracts the *intro opcon definition* from the *opcon structure*, ω, of the tycon structure, calling it σ_{def}. This is a static function that is applied, in the seventh premise, to determine whether the term is well-typed, raising an error if not or computing a translation if so. Its kind is checked by the judgement $\vdash_\Phi \omega \sim \psi$, which was the final premise of the rule (tcc-ext) and is defined in Figure 10. Rule (ocstruct-intro) specifies that it has access to the type index, the term index and an interface to the list of arguments, discussed below, and returns a *quoted translational internal term* of kind ITm, analagous to ITy. The intro opcon definitions for RSTR and LPROD are given in Figures 11 and 12.

Though the latter will be encountered first in our example derivation, let us first consider the intro opcon definition in Figure 11 because it is more straightforward. It will be used to analyze the row value $\mathsf{intro}[\texttt{"EXMPL 2015"}_{\text{SL}}](\cdot)$ against σ_{conf}. It begins by making sure that no arguments were passed in using the helper function ***arity0*** :: List[Arg] → 1 defined such that any non-empty list will raise an error, via the static term raise[1]. In practice, the tycon provider would specify an error message here. Next, it checks the string provided as the term index against the regular expression given as the type index using ***rmatch*** :: Rx → Str → 1, which

$\boxed{\Upsilon \vdash_\Phi e \Leftarrow \sigma \rightsquigarrow \iota^-}$ $\boxed{\Upsilon \vdash_\Phi e \Rightarrow \sigma \rightsquigarrow \iota^-}$

(subsume)
$$\frac{\Upsilon \vdash_\Phi e \Rightarrow \sigma \rightsquigarrow \iota}{\Upsilon \vdash_\Phi e \Leftarrow \sigma \rightsquigarrow \iota}$$

      let rowtr :: ITm = ana rowarg rowty in
      ▷((◁(rowtr), ◁(r)))
```

Figure 12. The intro opcon definition for LPROD, $\sigma_{\mathrm{lprod/intro}}$.

we assume is defined in the usual way and again raises an error on failure. Finally, the *translational internal string* corresponding to the static string provided as the term index is generated via the helper function ***str_of_Str*** :: Str → ITm.

Static terms of kind ITm are introduceed by the quotation form, $\rhd(\hat{\iota})$, where $\hat{\iota}$ is a *translational internal term*. This is analagous to the form $\blacktriangleright(\hat{\tau})$ for ITy in Sec. 3.4. Each form in the syntax of ι has a corresponding form in the syntax for $\hat{\iota}$ and the kinding rules and dynamics simply recurse through these in the same manner as in Sec. 3.4. There is also an analagous unquote form, $\lhd(\sigma)$. The two interesting forms of translational internal term are $\mathsf{anatrans}[n](\sigma)$ and $\mathsf{syntrans}[n]$. These stand in for the translation of argument n, the first if it arises via analysis against type σ and the second if it arises via type synthesis. Before giving the rules, let us motivate the mechanism with the intro opcon definition for LPROD, shown in Figure 12.

The first line checks that the type provided is inhabited, in this case by checking that there are no duplicate labels via the helper function ***uniqmap*** :: List[Lbl × Ty] → 1, raising an error if there are (we briefly discuss alternative strategies in the supplement). The rest of the definition folds over the three lists provided as input: the list mapping row labels to types provided as the type index, the list of labels provided as the term index, and the list of argument interfaces, which give access to the corresponding row values. We assume a straightforward helper function, ***fold3***, that raises an error if the three lists are not of the same length. The base case is the translational empty product.

The recursive case checks, for each row, that the label provided in the term index matches the label in the type index using helper function ***lbleq*** :: Lbl → Lbl → 1. Then, we request type analysis of the corresponding argument, ***rowarg***, against the type in the type index, ***rowty***, by writing ***ana rowarg rowty***. Here, ***ana*** is a helper function defined in Sec. 4.2 below that triggers type analysis of the provided argument. If this succeeds, it evaluates to a translational internal term of the form $\rhd(\mathsf{anatrans}[n](\sigma))$, where n is the position of ***rowarg*** in ***args*** and σ is the value of ***rowty***. If analysis fails, it raises an error. The final line constructs a nested tuple based on the row value's translation and the recursive result. Taken together, the translational internal term that will be generated for our example involving e_{paper} above is $\hat{\iota}_{\mathrm{paper}} := (\mathsf{anatrans}[0](\sigma_{\mathrm{title}}), (\mathsf{anatrans}[1](\sigma_{\mathrm{conf}}), ()))$, i.e. it simply recalls that the two arguments were analyzed against σ_{title} and σ_{conf}, without yet inserting their translations directly. This will be done after *translation validation*, triggered by the final premise of (ana-intro) and described in Sec. 4.3.

4.2 Argument Interfaces

The kind of *argument interfaces* is Arg := (Ty → ITm) × (1 → Ty × ITm), i.e. a product of functions, one for analysis and the other for synthesis. The helpers ***ana*** and ***syn*** only project them out, e.g. ***ana*** := λ***arg***::Arg.fst(***arg***). To actually perform analysis or

(k-ana)
$$\frac{n' < n \qquad \Delta\ \Gamma \vdash^{n}_{\Phi} \sigma :: \mathsf{Ty}}{\Delta\ \Gamma \vdash^{n}_{\Phi} \mathsf{ana}[n'](\sigma) :: \mathsf{ITm}}$$

(k-syn)
$$\frac{n' < n}{\Delta\ \Gamma \vdash^{n}_{\Phi} \mathsf{syn}[n'] :: \mathsf{Ty} \times \mathsf{ITm}}$$

Figure 13. Kinding for the SL-EL interface.

synthesis, we must provide a link between the dynamics of the static language and the EL's typing rules. This is purpose of the static forms $\mathsf{ana}[n](\sigma)$ and $\mathsf{syn}[n]$. When consider an argument list of length n, written $|\overline{e}| = n$, the opcon definition will receive a static list of length n where the jth entry is the argument interface $(\lambda \textbf{\textit{ty}}{::}\mathsf{Ty}.\mathsf{ana}[j](\textbf{\textit{ty}}), \lambda\_{::}\mathsf{1}.\mathsf{syn}[j])$. This *argument interface list* is generated by the judgement $\mathsf{args}(n) = \sigma_{\text{args}}$.

The index n on the kinding judgement is an upper bound on the argument index of terms of the form $\mathsf{ana}[n](\sigma)$ and $\mathsf{syn}[n]$, enforced in Figure 13. Thus, if $\mathsf{args}(n) = \sigma_{\text{args}}$ then $\emptyset\ \emptyset \vdash^{n}_{\Phi} \sigma_{\text{args}} :: \mathsf{List}[\mathsf{Arg}]$. The rule (ocstruct-intro) ruled out writing either of these forms explicitly in an opcon definition by checking against bound $n = 0$. This is to prevent out-of-bounds errors: tycon providers can only access these forms via the argument interface list, which has the correct length.

The static dynamics of $\mathsf{ana}[n](\sigma)$ are interesting. After normalizing σ, the argument environment, which contains the arguments themselves and the typing and tycon contexts, $\mathcal{A} ::= \overline{e}; \Upsilon; \Phi$, is consulted to analyze the nth argument against σ. If this succeeds, $\triangleright(\mathsf{anatrans}[n](\sigma))$ is generated:

(n-ana-success)
$$\frac{\sigma\ \mathtt{val}_{\overline{e};\Upsilon;\Phi} \qquad \mathsf{nth}[n](\overline{e}) = e \qquad \Upsilon \vdash_{\Phi} e \Leftarrow \sigma \rightsquigarrow \iota}{\mathsf{ana}[n](\sigma) \mapsto_{\overline{e};\Upsilon;\Phi} \triangleright(\mathsf{anatrans}[n](\sigma))}$$

If it fails, an error is raised:

(n-ana-fail)
$$\frac{\sigma\ \mathtt{val}_{\overline{e};\Upsilon;\Phi} \qquad \mathsf{nth}[n](\overline{e}) = e \qquad [\Upsilon \vdash_{\Phi} e \not\Leftarrow \sigma]}{\mathsf{ana}[n](\sigma)\ \mathtt{err}_{\overline{e};\Upsilon;\Phi}}$$

We write $[\Upsilon \vdash_{\Phi} e \not\Leftarrow \sigma]$ to indicate that e fails to analyze against σ. We do not define this inductively, so we also allow that this premise be omitted, leaving a non-deterministic semantics nevertheless sufficient for our metatheory.

The dynamics for $\mathsf{syn}[n]$ are analagous, evaluating to a pair $(\sigma, \triangleright(\mathsf{syntrans}[n]))$ where σ is the synthesized type.

The kinding rules also prevent these translational forms from being well-kinded when $n = 0$ and, like $\mathsf{trans}(\sigma)$ in Sec. 3.4, they are retained in values of kind ITm.

4.3 Translation Validation

The judgement $\vdash^{c}_{\mathcal{A}} \hat{\iota} : \sigma \rightsquigarrow \iota^{-}$, defined by a single rule in Figure 14 and appearing as the final premise of (ana-intro) and the other rules described below, is pronounced "translational internal term $\hat{\iota}$ generated by an opcon associated with tycon c under argument environment $\mathcal{A}$ for an operation with type σ is valid, so translation ι is produced". For example,

$$\vdash^{\text{LPROD}}_{(title;\texttt{"EXMPL 2015"});\Upsilon_{\text{ex}};\Phi_{\text{rstr}}\Phi_{\text{lprod}}} \hat{\iota}_{\text{paper}} : \sigma_{\text{paper}} \rightsquigarrow \iota_{\text{paper}}$$

The purpose of translation validation is to check that the generated translation will be well-typed *no matter what the translations of types other than those constructed by c are*.

The first premise generates the selectively abstracted type translation for σ given that c was the delegated tycon as described in Sec. 3.4.1. In our running example, this is $\tau_{\text{paper/abs}}$, i.e. $\alpha_0 \times (\alpha_1 \times 1)$.

The judgement $\hat{\iota} \parallel \mathcal{D}\ \mathcal{G} \hookrightarrow^{c}_{\mathcal{A}} \iota^{-} \parallel \mathcal{D}^{-}\ \mathcal{G}^{-}$, appearing as the next premise, relates a translational internal term $\hat{\iota}$ to an internal term ι called a *selectively abstracted term translation*, because all references to the translation of an argument (having any type) are replaced with a corresponding variable, x, which will be of the selectively abstracted type translation of the type of that argument. For our example,

$$\boxed{\vdash^{c}_{\mathcal{A}} \hat{\iota} : \sigma \rightsquigarrow \iota^{-}}$$

(validate-tr)
$$\frac{\mathsf{trans}(\sigma) \parallel \emptyset \hookrightarrow^{c}_{\Phi} \tau_{\text{abs}} \parallel \mathcal{D} \qquad \hat{\iota} \parallel \mathcal{D}\ \emptyset \hookrightarrow^{c}_{\overline{e};\Upsilon;\Phi} \iota_{\text{abs}} \parallel \mathcal{D}'\ \mathcal{G} \qquad \mathcal{D}' \rightsquigarrow \delta : \Delta_{\text{abs}} \qquad \mathcal{G} \rightsquigarrow \gamma : \Gamma_{\text{abs}} \qquad \Delta_{\text{abs}}\ \Gamma_{\text{abs}} \vdash \iota_{\text{abs}} : \tau_{\text{abs}}}{\vdash^{c}_{\overline{e};\Upsilon;\Phi} \hat{\iota} : \sigma \rightsquigarrow [\delta][\gamma]\iota_{\text{abs}}}$$

Figure 14. Translation Validation

$\hat{\iota}_{\text{paper}} \parallel \mathcal{D}_{\text{paper/abs}}\ \emptyset \hookrightarrow^{\text{LPROD}}_{(title;\texttt{"EXMPL 2015"});\Upsilon_{\text{ex}};\Phi_{\text{rstr}}\Phi_{\text{lprod}}} \iota_{\text{paper/abs}} \parallel \mathcal{D}_{\text{paper/abs}}\ \mathcal{G}_{\text{paper/abs}}$ where $\iota_{\text{paper/abs}} := (x_0, (x_1, ()))$.

The type translation store, $\mathcal{D}$, discussed previously, and term translation store, $\mathcal{G}$, track these correspondences. Term translation stores have syntax $\mathcal{G} ::= \emptyset \mid \mathcal{G}, n : \sigma \rightsquigarrow \iota / x : \tau$. Each entry can be read "argument n having type σ and translation ι appears as variable x with type τ". In the example above, $\mathcal{G}_{\text{paper/abs}} := 0 : \sigma_{\text{title}} \rightsquigarrow title/x_0 : \alpha_0, 1 : \sigma_{\text{conf}} \rightsquigarrow \texttt{"EXMPL 2015"}_{\text{IL}}/x_1 : \alpha_1$.

To derive this, the judgement proceeded recursively along shared forms, as in Sec. 3.4.1. The interesting rule for argument translations derived via analysis is below ($\mathsf{syntrans}[n]$ is analagous; see supplement):

(abs-anatrans-new)
$$\frac{n \notin \mathrm{dom}(\mathcal{G}) \qquad \mathsf{nth}[n](\overline{e}) = e \qquad \Upsilon \vdash_{\Phi} e \Leftarrow \sigma \rightsquigarrow \iota \qquad \mathsf{trans}(\sigma) \parallel \mathcal{D} \hookrightarrow^{c}_{\Phi} \tau \parallel \mathcal{D}' \qquad (x \text{ fresh})}{\mathsf{anatrans}[n](\sigma) \parallel \mathcal{D}\ \mathcal{G} \hookrightarrow^{c}_{\overline{e};\Upsilon;\Phi} x \parallel \mathcal{D}'\ \mathcal{G}, n : \sigma \rightsquigarrow \iota / x : \tau}$$

The third premise of (validate-tr) generates the type substitution and type formation contexts implied by the final type translation store as described in Sec. 3.4.1. Similarly, each term translation store $\mathcal{G}$ implies an internal term substitution, $\gamma ::= \emptyset \mid \gamma, \iota/x$, and corresponding Γ by the judgement $\mathcal{G} \rightsquigarrow \gamma : \Gamma$, appearing as the fourth premise. Here, $\gamma_{\text{paper/abs}} := title/x_0, \texttt{"EXMPL 2015"}_{\text{IL}}/x_1$ and $\Gamma_{\text{paper/abs}} := x_0 : \alpha_0, x_1 : \alpha_1$.

The critical fifth premise checks the selectively abstracted term translation $\iota_{\text{paper/abs}}$ against the selectively abstracted type translation $\tau_{\text{paper/abs}}$ under these contexts via the internal statics. Here, $\Delta_{\text{paper/abs}}\ \Gamma_{\text{paper/abs}} \vdash \iota_{\text{paper/abs}} : \tau_{\text{paper/abs}}$, i.e.:

$$(\alpha_0, \alpha_1)\ (x_0 : \alpha_0, x_1 : \alpha_1) \vdash (x_0, (x_1, ())) : \alpha_0 \times (\alpha_1 \times 1)$$

In summary, the translation of the labeled product e_{paper} generated by LPROD is checked with the references to term and type translations of regular strings replaced by variables and type variables, respectively. But because the definition treated arguments parametrically, the check succeeds.

Applying the substitutions $\gamma_{\text{paper/abs}}$ and $\delta_{\text{paper/abs}}$ in the conclusion of the rule, we arrive at the actual term translation $\iota_{\text{paper}} := (title, (\texttt{"EXMPL 2015"}_{\text{IL}}, ()))$. Note that ι_{paper} has type τ_{paper} under the translation of Υ_{ex}, i.e. $\vdash \Upsilon_{\text{ex}}\ \mathtt{ctx} \rightsquigarrow \Gamma_{\text{ex}}$ where $\Gamma_{\text{ex}} := title : \mathsf{str}$. This relationship will always hold, and implies type safety (Sec. 5).

Had we attempted to "smuggle out" a value of regular string type that violated the regular string invariant, e.g. generating $\hat{\iota}_{\text{bad}} := (\texttt{""}, (\texttt{""}, ()))$, it would fail, because even though $(\texttt{""}_{\text{IL}}, (\texttt{""}_{\text{IL}}, ())) : \mathsf{str} \times \mathsf{str} \times 1$, it is not the case that $(\texttt{""}_{\text{IL}}, (\texttt{""}_{\text{IL}}, ())) : \alpha_0 \times (\alpha_1 \times 1)$. We call this property *translation independence*.

4.4 Generalized Targeted Operations

All non-introductory operations go through the form for *targeted operations*, $\mathsf{targop}[\textbf{op}; \sigma_{\text{tmidx}}](e_{\text{targ}}; \overline{e})$, where **op** is the opcon name, σ_{tmidx} is the term index, e_{targ} is the *target argument* and $\overline{e}$ are the remaining arguments. Concrete desugarings for this form include $e_{\text{targ}}.\textbf{op}\langle\sigma_{\text{tmidx}}\rangle(\overline{e})$ (and variants where the term index or arguments are omitted), projection syntax for use by record-like types, $e_{\text{targ}}\texttt{\#lbl}$, which desugars to $\mathsf{targop}[\texttt{\#}; \texttt{lbl}](e_{\text{targ}}; \cdot)$, and $e_{\text{targ}} \cdot e_{\text{arg}}$, which desugars to $\mathsf{targop}[\textbf{conc}; ()](e_{\text{targ}}; e_{\text{arg}})$. We show other desugarings, e.g. case analysis, in the supplement.

```
syn conc = λtyidx::Rx.λtmidx::1.λargs::List[Arg].
  letpair (arg1, arg2) = arity2 args in
  letpair (_, tr1) = syn arg1 in
  letpair (ty2, tr2) = syn arg2
  tycase[RSTR](ty2; tyidx2.
    (RSTR⟨rxconcat tyidx tyidx2⟩, ▷(sconcat ◁(tr1) ◁(tr2)))
  ; raise[Ty × ITm])
```

Figure 15. A targeted opcon definition, $\sigma_{\text{rstr/conc}}$.

Whereas introductory operations were analytic, targeted operations are synthetic in λ_{Verse}. The type and translation are determined by the tycon of the type synthesized by the target argument. The rule (syn-targ) is otherwise similar to (ana-intro) in its structure. The first premise synthesizes a type, $\text{TC}\langle\sigma_{\text{tyidx}}\rangle$, for the target argument. The second premise extracts the tycon definition for TC from the tycon context. The third extracts the *operator index kind* from its opcon signature, and the fourth checks the term index against it.

Figure 7 showed portions of the opcon signatures of RSTR and LPROD. The opcons associated with RSTR are taken directly from Fulton et al.'s specification of regular string types [18], with the exception of **case**, which generalizes case analysis as defined there to arbitrary string patterns, based on the form of desugaring we show in the supplement. The opcons associated with LPROD are also straightforward: **#** projects out the row with the provided label and **conc** concatenates two labeled products (updating common rows with the value from the right argument). Note that both RSTR and LPROD can define concatenation.

The fifth premise of (syn-targ) extracts the *targeted opcon definition* of **op** from the opcon structure, ω. Like the intro opcon definition, this is a static function that generates a translational internal term on the basis of the target tycon's type index, the term index and an argument interface list. Targeted opcon definitions additionally synthesize a type. The rule (ocstruct-targ) in Figure 10 ensures that it is well-kinded. For example, the definition of RSTR's **conc** opcon is shown in Figure 15 (others will be in the supplement).

The helper function ***arity2*** checks that two arguments, including the target argument, were provided. We then request synthesis of both arguments. We can ignore the type synthesized by the first because by definition it is a regular string type with type index ***tyidx***. We case analyze the second against RSTR, to extract its index regular expression (raising an error if it is not of regular string type). We then synthesize the resulting regular string type, using the helper function ***rxconcat*** :: Rx → Rx → Rx which generates the synthesized type's index by concatenating the indices of the argument's types consistent with the specification in [18]. Finally the translation is generated using helper function $sconcat$: str → str → str, the translational term for which we assume has been substituted in directly.

The last premise of (syn-targ) again performs translation validation as described above. The only difference relative to (ana-intro) is that that we check the term translation against the synthesized type but the delegated tycon is that of the type synthesized by the target argument.

4.5 Operations Over Other Types

The rules (ana-intro-other) and (syn-targ-other) are used to introduce and simulate targeted operations on terms of all types constructed by any "other" tycon. In both cases, the term index, rather than the tycon context, directly specifies the translational internal term to be used.

5. Metatheory

We will now state the key metatheoretic properties of λ_{Verse}. The proofs (with a few straightforward details left to be fleshed out) are in the supplement.

Kind Safety Kind safety ensures that normalization of well-kinded static terms cannot go wrong. We can take a standard progress and preservation based approach.

Theorem 1 (Static Progress)**.** *If* $\emptyset\ \emptyset \vdash^n_\Phi \sigma :: \kappa$ *and* $|\overline{e}| = n$ *then* $\sigma \mapsto_{\overline{e};\Upsilon;\Phi} \sigma'$ *or* $\sigma\ \texttt{val}_{\overline{e};\Upsilon;\Phi}$ *or* $\sigma\ \texttt{err}_{\overline{e};\Upsilon;\Phi}$.

Theorem 2 (Static Preservation)**.** *If* $\emptyset\ \emptyset \vdash^n_\Phi \sigma :: \kappa$ *and* $\vdash \Phi$ *and* $\vdash_\Phi \Upsilon\ \texttt{ctx} \rightsquigarrow \Gamma$ *and* $\sigma \mapsto_{\overline{e};\Upsilon;\Phi} \sigma'$ *then* $\emptyset\ \emptyset \vdash^n_\Phi \sigma' :: \kappa$.

The case in the proof of Theorem 2 for $\sigma = \texttt{syn}[n]$ requires that the following theorem be mutually defined.

Theorem 3 (Type Synthesis)**.** *If* $\vdash \Phi$ *and* $\vdash_\Phi \Upsilon\ \texttt{ctx} \rightsquigarrow \Gamma$ *and* $\Upsilon \vdash_\Phi e \Rightarrow \sigma \rightsquigarrow \iota$ *then* $\sigma\ \texttt{type}_\Phi$.

Type Safety Type safety in a typed translation semantics requires that well-typed external terms translate to well-typed internal terms. Type safety for the IL [20] then implies that evaluation cannot go wrong. To prove this, we must in fact prove a stronger theorem: that a term's translation has its type's translation under the typing context's translation (the analagous notion is *type-preserving compilation* in type-directed compilers [46]):

Theorem 4 (Type-Preserving Translation)**.** *If* $\vdash \Phi$ *and* $\vdash_\Phi \Upsilon\ \texttt{ctx} \rightsquigarrow \Gamma$ *and* $\vdash_\Phi \sigma\ \texttt{type} \rightsquigarrow \tau$ *and* $\Upsilon \vdash_\Phi e \Leftarrow \sigma \rightsquigarrow \iota$ *then* $\emptyset \vdash \Gamma$ *and* $\emptyset \vdash \tau$ *and* $\emptyset\ \Gamma \vdash \iota : \tau$.

Proof Sketch. The interesting cases are (ana-intro), (ana-intro-other), (syn-trans) and (syn-trans-other); the latter two arise via subsumption. The result follows directly from the translation validation process, combined with lemmas that state that all variables in Δ_{abs} and Γ_{abs} in (tr-validate) have well-formed/well-typed substitutions in δ and γ, so applying in the conclusion them gives a well-typed term. □

Hygienic Translation Note above that the domains of Υ (and thus Γ) and Γ_{abs} are disjoint. This serves to ensure *hygienic translation* – translations cannot refer to variables in the surrounding scope directly, so uniformly renaming a variable cannot change the meaning of a program. Variables in Υ can occur in arguments (e.g. $title$ in the earlier example), but the translations of the arguments only appear *after* the substitution γ has been applied. We assume that substitution is capture-avoiding in the usual manner.

Conservativity Extending the tycon context also conserves all *tycon invariants* maintained in the original tycon context. An example of a tycon invariant is the following:

Tycon Invariant 1 (Regular String Soundness)**.** *If* $\emptyset \vdash_{\Phi_{rstr}} e \Leftarrow \text{RSTR}\langle\texttt{/r/}\rangle \rightsquigarrow \iota$ *and* $\iota \Downarrow \iota'$ *then* $\iota' = \texttt{"s"}$ *and* $\texttt{"s"}$ *is in the regular language* $\mathcal{L}(\texttt{r})$.

Proof Sketch. We have fixed the tycon context Φ_{rstr}, so we can essentially treat the calculus like a type-directed compiler for a calculus with only two tycons, ⇀ and RSTR, plus some "other" one. Such a calculus and compiler specification was given in [18], so we must simply show that the opcon definitions in RSTR adequately satisfy these specification using standard techniques for the SL, a simply-typed functional language [10]. The only "twist" is that the rule (syn-targ-other) can synthesize a regular string type paired with any translational term $\hat{\tau}$. But it will be validated against $\tau_{\text{abs}} = \alpha$ because rule (abs-ext-not-delegated-new) applies in that case. Thus, the invariants cannot be violated by direct application of parametricity in the IL (i.e. this case can always be dispatched via a "free theorem") [47]. □

Another way to interpret this argument is that "other" types simulate all types that might arise from "the future" in that they can have any valid type translation (given directly in the type index) and their operators can produce any valid term translation (given directly in the term index). Because they are distinct from all "present" tycons, our translation validation procedure ensures that they can be reasoned about uniformly – they cannot possibly violate present invariants because they do not even know what type of term they need to generate. The only way to generate a term of type α is via an argument, which inductively obeys all tycon invariants.

Theorem 5 (Conservativity)**.** *If* $\vdash \Phi$ *and* $\text{TC} \in \mathit{dom}(\Phi)$ *and a tycon invariant for* TC *holds under* Φ*:*

- *For all* $\Upsilon, e, \sigma_{\mathit{tyidx}}$*, if* $\Upsilon \vdash_\Phi e \Leftarrow \text{TC}\langle\sigma_{\mathit{tyidx}}\rangle \rightsquigarrow \iota$ *and* $\vdash_\Phi \Upsilon\ \texttt{ctx} \rightsquigarrow \Gamma$ *and* $\vdash_\Phi \text{TC}\langle\sigma_{\mathit{tyidx}}\rangle \rightsquigarrow \tau$ *then* $P(\Gamma, \sigma_{\mathit{tyidx}}, \iota)$*.*

then for all $\Phi' = \Phi, \mathsf{tycon}\ \text{TC}'\ \{\theta'\} \sim \mathsf{tcsig}[\kappa']\ \{\chi'\}$ *such that* $\vdash \Phi'$*, the same tycon invariant holds under* Φ'*:*

- *For all* $\Upsilon, e, \sigma_{\mathit{tyidx}}$*, if* $\Upsilon \vdash_{\Phi'} e \Leftarrow \text{TC}\langle\sigma_{\mathit{tyidx}}\rangle \rightsquigarrow \iota$ *and* $\vdash_{\Phi'} \Upsilon \rightsquigarrow \Gamma$ *and* $\vdash_{\Phi'} \text{TC}\langle\sigma_{\mathit{tyidx}}\rangle \rightsquigarrow \tau$ *then* $P(\Gamma, \sigma_{\mathit{tyidx}}, \iota)$*.*

(if proposition $P(\Gamma, \sigma, \iota)$ *is* modular*, defined below)*

Proof Sketch. Our proof of the more general property is a realization of this intuition that "other" types simulate future types. We simply map every well-typed term under Φ' to a well-typed term under Φ with the same translation, and if the term has a type constructed by a tycon in Φ, e.g. TC, the new term has a type constructed by that tycon with the same type translation, and only a slightly different type index. In particular, the mapping's effect on static terms is to replace all types constructed by TC' with a type constructed by $\texttt{other}[m; \kappa'_{\text{tyidx}}]$. If $P(\Gamma, \sigma_{\text{tyidx}}, \iota)$ is preserved under this transformation on σ_{tyidx} then we can simply invoke the existing proof of the tycon invariant. We call such propositions *modular*. Non-modular propositions are uninteresting because they distinguish tycons "from the future". Our regular string proposition is clearly modular because regular expressions don't contain types at all.

On external terms, the mapping replaces all intro and targeted terms that delegated to TC' with equivalent ones that pass through rules (ana-intro-other) and (syn-targ-other) by pre-applying the intro and targeted opcon definitions to generate the term indices. □

6. Related Work and Discussion

We are not the first to use a semantics distinguishing the EL from a smaller IL for a language specification. For example, the Harper-Stone semantics for Standard ML takes a similar approach, though the EL and IL are governed by a common, and fixed, type system there [21]. Our specification style is also comparable to that of the initial stage of a type-directed compiler, e.g. the TIL compiler for Standard ML [46], here lifted "one level up" into the semantics of the language itself and made extensible.

Language-integrated static term rewriting systems, like Template Haskell [45] and Scala's static macros [8], can be used to decrease complexity when an isomorphic embedding into the underlying type system is already possible. Similarly, when an embedding that preserves a fragment's static semantics exists, but a different embedding better approaches a desired cost semantics, term rewriting can also be used to perform "optimizations". Care is needed when this changes the type of a term. Type abstraction has been used for this purpose in work on *lightweight modular staging* (LMS) [41]. In all of these cases, the type system remains fixed.

When new static distinctions are needed within an existing type, but new operators are not necessary, one solution is to develop an overlying system of *refinement types* [17]. For example, a refinement of integers might distinguish negative integers. Proposals for "pluggable type systems" describe composing such systems [3, 6]. Refinements of abstract types can be used for representation independence, but note that the type being refined is not held abstract. Were it to be, the system could be seen in ways as a degenerate mode of use of our work: we further cover the cases when new operators are needed. For example, labeled tuples couldn't be seen as refinements of nested pairs because label-indexed row projection operators simply don't exist.

Many *language frameworks* exist that simplify dialect implementation (cf. [16]). These sometimes do not support forming languages from fragments due to the "expression problem" (EP) [39, 48]. We sidestep the most serious consequences of the EP by leaving our abstract syntax entirely fixed, instead delegating to tycons. Fewer tools require knowledge of all external tycons in a typed translation semantics. Some language frameworks do address the EP, e.g. by encoding terms and types as open datatypes [27], but this makes it quite difficult to reason modularly, particularly about metatheoretic properties specific to typed languages, like type safety and tycon invariants. Our key insight is to instead associate term-level opcons with tycons, which then become the fundamental constituents of the semantics (consistent with Harper's informal notation from Sec. 1).

As discussed, our treatment of concrete syntax defers to recent work on *type-specific languages*, which takes a similar split bidirectional approach for composably introducing syntax [35]. We focus on semantics.

Proof assistants can be used to specify and mechanize the metatheory of languages, but also usually require a complete specification (this has been identified as a key challenge [4]). Techniques for composing specifications and proofs exist [14, 15, 44], but they require additional proofs at composition-time and provide no guarantees that *all* fragments having some modularly checkable property can safely and conservatively be composed, as in our work. Several authors, notably Chlipala [11], suggest proof automation as a heuristic solution to the problem.

In contrast, in λ_{Verse}, fragment providers need not provide the semantics with mechanized specfications or proofs to benefit from rigorous modular reasoning principles. Instead, under a fixed tycon context, the calculus can be reasoned about like a very small type-directed compiler [10, 13, 46]. Errors in reasoning can only lead to failure at typechecking time, via our chief contribution: a novel form of *translation validation* [38]. Incorrect opcon definitions relative to a specification (e.g. [18] for regular strings) can at worst weaken expected invariants at that tycon, like incorrectly implemented modules in ML. Thus, modular tycons can reasonably be tested "in the field" without concern about the reliability of the semantics as a whole. To eliminate even these localized failure modes, we plan to introduce *optional* specification and proof mechanization into the SL (by basing it on a dependently typed language like Coq, rather than ML). Because types are values in the SL, the SL can be seen as building on the concept of *type-level computation*.

Type abstraction, encouragingly, also underlies modular reasoning in ML-like languages [19, 20] and languages with other forms of ADTs [26] like Scala [2]. Indeed, proofs of tycon invariants can rely on existing parametricity theorems [47]. Our work is thus reminiscent of work on elaborating an ML-style module system into System $\mathbf{F}_\omega$ [43]. Unlike in module systems, type translations (analagous to the choice of representation for an abstract type) are statically *computed* based on a type index, rather than statically *declared*. Moreover, there can be arbitrarily many operators because they arise by providing a term index to an opcon, and their semantics can be complex because a static function computes the types and translations that arise. In contrast, modules and ADTs can only specify a fixed number of operations, and each must

have function type. Note also that these are not competing mechanisms: we did not specify quantification over external types here for simplicity, but we conjecture, based on the finding that polymorphism is conservative over simple types, [7], that this is complementary and thus λ_{Verse} could serve as the core of a language with an ML-style module system and polymorphism. Another related direction is to explore *tycon functors*, which would abstract over tycons with the same signature to support modularly tunable cost semantics.

7. Conclusion

We have specified a simple but surprisingly powerful language, Verse, specified at its core by a typed translation semantics, λ_{Verse}, where new type constructors can be introduced "from within". The corresponding operator constructors determine types and translations "actively", i.e. using static functions. A simple form of translation validation based on existing notions of type abstraction ensures that opcons associated with one tycon maintain translation independence from all others, guaranteeing that a wide class of important properties can be reasoned about modularly. Implementation in several settings is ongoing.

A limitation of our approach is that it supports only fragments with the standard "shape" of typing judgement. Fragments that require new forms of scoped contexts (e.g. symbol contexts [20]) cannot presently be defined. Relatedly, the language controls variable binding, so, for example, linear type systems cannot be defined. Another limitation is that opcons cannot directly invoke one another (e.g. a **len** opcon on regular strings could not construct a natural number). We conjecture that these are not fundamental limitations and expect λ_{Verse} to serve as a foundation for future efforts that increase expressiveness while maintaining the strong modularity guarantees established here.
