# Safely Extending Typed Programming Systems From Within (Thesis Proposal)

Cyrus Omar Computer Science Department Carnegie Mellon University comar@cs.cmu.edu

### **Abstract**

We propose a thesis defending the following statement:

Typed programming systems can be made more expressive by incorporating *extension mechanisms* that allow library providers to introduce new syntax, type system fragments and editor services. The code that extensions generate can be validated to preserve key metatheoretic properties, and to guarantee that extensions can be reasoned about separately and composed arbitrarily.

### 1 Motivation

The recent development of programming languages suggests that the simultaneous achievement of simplicity and generality in language design is a serious unsolved problem. – John Reynolds, 1970 [30]

Achieving both simplicity and generality in the design of a programming language and its associated tools (collectively, a *programming system*) requires organizing around a small number of mechanisms that support the expression of many others as libraries. Much progress has been made in the decades since Reynolds' statement above, but across all language lineages, new language and tool *dialects* remain common vehicles for new ideas, both in research and practice. This suggests that library-based mechanisms are still not general enough to encompass many desirable modes of expression.

We will consider the broad class of situations where providers need to introduce new concrete syntax, type system fragments, or editor services into a system to realize an idea. Equipping the system with *extension mechanisms* that decentralize control over these features would decrease the need for dialects, but this must done with care, because giving away too much control could also weaken the metatheory of the system. For example, were extensions allowed to arbitrarily modify the type system of the language, there would be immediate questions about type safety. Moreover, extension mechanisms must come with *modular reasoning principles* for it to be practical for library clients to rely upon them. Having to resolve conflicts between extensions or reestablish correctness properties of a program whenever a new extension is imported is unacceptably complex.

In this thesis, we will design extension mechanisms that handle these issues, permitting library-based expression of features that today would need to be built into a system by its central designers. More specifically, we show how to delegate control over certain aspects of the concrete syntax, static semantics and editor services to *static functions*, i.e. user-defined functions written in a *static language*. By layering these mechanisms over a fixed typed internal language, constraining the static language appropriately and validating the code it is used to generate, we will retain key metatheoretic properties and arrive at powerful modular reasoning principles.

### 1.1 Motivating Examples

To make the use cases we seek to address more concrete, we begin with a few examples of system features that we wish to make expressible.

### 1.1.1 Example 1: Regular Expressions

Regular expressions are commonly used to capture patterns in strings (e.g. motifs in DNA sequences) [34]. Programmers who work with regular expressions would benefit from features like these:

1. **Concrete syntax for pattern literals**. An ideal syntax would permit programmers to express patterns in the concise, conventional manner. For example, consider a bioinformatics application: the BisI restriction enzyme cuts DNA when it sees the motif GCNGC, where N is any base. We would want to express such patterns with syntax like the following, where we use curly braces to splice one pattern into another and parentheses to delimit captured groups:

```
let N : Pattern = <A|T|G|C>
let BisI : Pattern = <GC({N})GC>
```

Malformed patterns, e.g. <GC(> must result in intelligible *compile-time* parse errors no matter where they appear in a program.

- 2. A **static semantics** that ensures that key invariants related to regular expressions are statically maintained. For example,
  - (a) At minimum, we would want that only patterns, or properly escaped strings, are spliced into a pattern literal, to avoid splicing errors and injection attacks [4, 6]. For example,

```
let fourChars : string = '\d\d'
let twoDigits : Pattern = <\d\d>
let p : Pattern = <{fourChars}-{twoDigits}>
```

should either be ill-typed because fourChars is not a pattern, or be equivalent to the following:

```
let p : Pattern = < \d \d \d >
```

It should *not* treat the string incorrectly as a pattern:

```
let p : Pattern = <\d^-\d^-\ (* injection attack vector! *)
```

- (b) A more advanced semantics might ensure that out-of-bounds backreferences to a captured group do not occur [32]. For example, we would want BisI, above, to have the more precise type Pattern[1], i.e. a pattern with one captured group.
- 3. A range of **editor services** that support syntax highlighting for patterns, retrieval of relevant documentation, interactive testing and pattern extraction from example strings have been shown to be helpful for programmers when working with complex regular expressions [26]. An example of some of these is shown in Figure 1: the editor service shown helps programmers generate correct code, here via the Java standard library's implementation of regular expressions (discussed below).

No system today provides built-in support for all of the features enumerated above in their strongest form, so library providers must leverage general-purpose mechanisms.

The most common strategy, exemplified by Java, is to ask clients to introduce patterns as strings, deferring their parsing and compilation to run-time. This provides only a partial approximation to feature 1 due to clashes between string escape sequences and pattern escape sequences, as can be seen in the generated code at the bottom of Figure 1

```
import java.util.regex.Pattern;
public class Matcher {
   public static boolean isTemperature(String s) {
             Pattern p =
                                                                                                                                                          ■ Ignore Case Pattern Description
                                        ^-?(\d+|(\d*(\.\d+)))?\s?(F|C)$
                                                                                                                                                                                         regex
regex$
[abc]
                                                                                                                                                                                                     Must match at the beginning of the line
Must match at the end of the line
Set definition, matches the letter a or b
                                                                                                                 Should NOT match
                                        37F
                                                                                                                 12:05
                                        42.1 F
                                                                                                                                                                                         or c
[abc][vz] Set definition, matches a or b or c
                                                                                                                 37
                                                                                                                                                                                                     followed by v or z
Negates the pattern. Matches any
                                         .8C
                                                                                                                 37Q
                                                                                                                                                                                         [^abc]
                                                                                                                                                                                        (Pabc) Negates the pattern. Matches any character except a or b or c [a-d1-7] Ranges, letter between a and d or digits from 1 to 7, will not match d1 XIZ Finds X or Z YZ Finds X directly followed by Z | d Any digit, short for [0-9] | D A non-digit, short for [^0-9]

import java.util.regex.Pattern;
public class Matcher {
       public static boolean isTemperature(String.s) {
   Pattern p = Pattern.compile("^-?(\\d+|(\\d*(\\.\\d+)))?\\s?(FIC)$");
                 * Should match:
                       37F
                       42.1 F
                        -100
                    Should NOT match:
                       12:05
                       37Q
```

Figure 1: An example of type-specific editor services, here shown for Java.

(double backslashes are needed). Parsing errors due to these clashes have been observed to be difficult for even experienced programmers to diagnose [27]. Moreover, the static semantics described in feature 2 cannot be expressed, leading to run-time exceptions (even in well-tested code using regular expressions [32]), and mistakes that cannot be caught even with run-time checks. This can lead to security vulnerabilities due to injection attacks, a widespread contemporary problem [4]. It also introduces performance overhead due to run-time parsing and compilation of patterns.

A more semantically justifiable approach is to dispense with string representations entirely and directly work with an encoding of regular expression patterns using general-purpose constructs like recursive sums and products (e.g. as exposed by datatypes in a functional language, shown in Sec. 3, or a class hierarchy in an object-oriented language), or using an abstract data type. This provides feature 2a at the expense of feature 1 (such an encoding affords only an approximation of the verbose abstract syntax of patterns, not the concrete syntax above). Advanced invariants like those described in feature 2b are not directly tracked by the simplest such encodings (languages with support for GADTs could be used in this particular case [36]).

None of these approaches address the important issue of tool support (feature 3). A number of tools are available online that provide services ranging from simple syntax highlighting to interactive testing and explanations of complex patterns [2] and pattern extraction from examples [3]. We have found that programmers benefit substantially from their use [27]. Unfortunately, evidence suggests that tools that must be accessed externally are difficult to discover and are thus used infrequently [23, 8, 27]. We have found that they are also less usable than editor-integrated tools because they require the programmer to switch contexts and cannot make use of the code context [27]. For these reasons, we see editor services as within the broad scope of an abstraction specification.

### 1.1.2 Example 2: Regular Strings

The example above dealt with how regular expression patterns are represented. However, programmers also want to reason about which regular language a string value is in [15]. For example, we might want to ensure that the arguments to a function that creates a database connection given a username and password are only alphanumeric strings. We would ideally include this information directly in the type of the function:

```
type alphanumeric = rstring[<[A-Za-z0-9]+>]
val connect : (alphanumeric * alphanumeric) -> DBConnection
```

This example assumes that the language includes a *type constructor*, rstring, indexed by a statically known regular expression, written using the syntax described above. Ideally, we would be able to use standard string literal syntax for such regular strings:

```
let connection = connect("admin", "password")
```

To be useful, the language would need to come equipped with a static semantics that continues to track the regular language a string is in through standard string operations. For example, a regular string introduced by concatenating two other alphanumeric strings should also be an alphanumeric string. All such operations should have the same or lower cost when compared to the corresponding operations on standard strings.

Regular strings might go beyond simply *refining* standard string types (i.e. specifying verification conditions atop an existing semantics) [14]. For example, they might define an operation like *captured group projection* that cannot be defined for strings:

```
let example : rstring[<(\d\d\d)-(\d\d\d)>] = "555-5555" let group0 (* : rstring[<\d\d\d>] *) = example#0
```

It should be possible to give this operation a cost of  $\mathcal{O}(1)$ . From a language implementation perspective, this requires that different regular string types have different representations, also not possible when using a refinement system over strings.

### 1.1.3 Example 3: Labeled Products with Functional Update Operators

The simplest way to specify the semantics of product types is to define only nullary and binary products [16]. However, in practice, many variations on product types are built in to various dialects of ML and other languages: *n*-ary tuples, labeled tuples, records (identified up to reordering), and records with width and depth coercions [9] and functional update operators (also called *extensible records*) [19]. The Haskell wiki notes that "extensible records are not implemented in GHC. The problem is that the record design space is large, and seems to lack local optima. [...] As a result, nothing much happens." [1]

We would ideally like to avoid needing the language designer to decide *a priori* on just one privileged point in this large design space. Instead, they should simply provide some minimal mechanism for defining products of values, e.g. only nullary and binary products, and include a mechanism that makes it possible for these other variations on products to be defined as libraries and then used together without conflict. For example, we would like to define the semantics of labeled tuples, which have labeled rows like records but maintain a row ordering like tuples, in a library. An example of a labeled product type classifying conference papers might be:

```
type Paper = lprod[{
  title : rstring[<.+>],
  conf : rstring[<[A-Z]+ \d\d\d\d>]
}
```

The row ordering should make it possible to introduce values of this type with or without explicit labels, e.g.

```
fun make_paper(t : rstring[<.+>]) : Paper = {title=t, conf="EXMPL 2015"}
should be equivalent to
fun make_paper(t : rstring[<.+>]) : Paper = (t, "EXMPL 2015")
```

Note that we aim to be able to unambiguously re-use standard record and tuple syntax. We should then be able to project out rows by providing a label:

```
let test_paper = make_paper "Test Paper"
test_paper#conf
```

We might also wish for our labeled tuples to support functional update. For example, an operation that dropped a row might be used like this:

```
let title_only (* : lprod[{title : rstring[<.+>]}] *) = test_paper.drop[conf]
An operation that added a row, or updated an existing row, might be used like this:
```

```
fun with_author(p : Paper, a : rstring[<.+>]) = p.ext(author=a)
```

## 1.2 Language-External Approaches

In situations like these where a library-based approach is not satisfying, providers must today take a *language-external approach*, specifying a new system dialect and implementing it using a *compiler generator* [7], *language workbench* [11], *DSL framework* [13], using an extension mechanism for a particular compiler<sup>1</sup>, editor or other tool, or by forking an existing implementation. For example, a researcher interested in providing the regular expression related features just described (let us refer to these collectively as R) might design a new system with built-in support for them, perhaps basing it on an existing system containing some general-purpose features (G, e.g. the features of Standard ML). A different researcher developing a new language-integrated parallel programming abstraction (P) might take the same approach (e.g. Manticore is such a system [12]). A third researcher, developing a type system for reasoning about units of measure (Q) might again do the same [18]. This results in a collection of distinct systems, as diagrammed in Figure 2a.

Although often justified as "proofs of concept", this is a rather weak notion because no abstraction will be used entirely in isolation and such a construction gives us no rigorously justifiable reason to believe that it can safely and naturally coexist with others specified or implemented in the same way. That is, one must either use the system containing features G+R, G+P or G+Q. There is no system containing G, R, P and Q in other combinations, and merging the systems defining each separately can be non-trivial because there can be serious interference and safety issues, as we will discuss at length throughout this thesis.

# 1.3 Language-Integrated Approaches

We argue that, due to these problems of composition, taking a language-external approach to realizing a new feature should be considered harmful and avoided whenever possible. The goal of the research being proposed here is to design *language-integrated extension mechanisms* that give providers the ability to define, within libraries, new features like those above that have previously required central planning, so that language-external approaches are less frequently necessary. The concept is illustrated in Figure 2b.

We must proceed with caution, however: critical issues having to do with safety must be overcome before language-integrated extension mechanisms can be introduced into a system. If too much control over these core features of the system is given to developers, the system's metatheory may become weak. For example, parsing ambiguities might arise if the syntax can be modified arbitrarily. Type safety may not hold if the static and dynamic semantics of the language can be modified or extended arbitrarily from within libraries. Furthermore, even if extensions can be shown not to cause such problems in isolation, there may still be conflicts between extensions that could weaken their semantics, leading to subtle problems that only appear when two extensions are used together. These issues have plagued previous attempts to design language-integrated extensibility mechanisms.

I can include a more detailed related work section if requested.

<sup>&</sup>lt;sup>1</sup>Compilers that modify, or allow modification of, the semantics of their base language, rather than simply permitting semantics-preserving optimizations, should be considered a pernicious means for creating new language dialects.

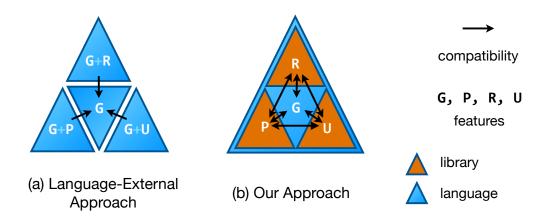

Figure 2: (a) When taking a language-external approach, new features are packaged together into separate languages and tools. (b) We propose an approach where there is one extensible host language and the compile-time and edit-time logic governing new constructs is expressed within safely composable libraries.

# 2 Proposed Contributions

This thesis will introduce several language-integrated extensibility mechanisms that decentralize control over a different feature of the system, all relying on a form of static elaboration from an *external language* (EL) to a fixed typed *internal language* (IL) controlled by user-defined functions written in a *static language* (SL).

- In Sec. 3, we will develop mechanisms that support extensible concrete syntax over a fixed general-purpose semantics.
- In Sec. 4, we will then give the EL its own extensible semantics where it possible to define new type constructors and their associated operators, like those described in Sec. 1.1.2 and 1.1.3, in a modular manner.
- In Sec. 5, we will then describe a mechanism called *active code completion* that supports specialized editor services, made available via the code completion menu in typeaware editors like Eclipse. The screenshot in Figure 1 is taken from this work.

In each case, we will show that the system retains important metatheoretic properties and that extensions can be reasoned about separately, in ways that we will make more precise as we go on, and composed arbitrarily. This will be possible because we constrain the SL and validate the code it generates by various criteria (at minimum, we check for well-typedness in all cases).

To justify the claim of expressiveness in the thesis statement, we will give a number of examples of non-trivial features that are, or would need to be, built into conventional systems, but that can be expressed within libraries using the mechanisms we introduce. To help us gather a broad, unbiased collection of examples and demonstrate the scope and applicability of our approaches in practice, we will also conduct small empirical studies when appropriate (though the primary contributions of this work are technical).

```
casetype Pattern (* case types are like ML datatypes *)
     Empty
     Str of string
     Seq of Pattern * Pattern
4
     Or of Pattern * Pattern
6
     Star of Pattern
     metadata = new (* new simply introduces a Wyvern object; objects are record-like *)
       val parser : Parser = new (* rows, called fields, are defined with val... *)
         \mbox{\bf def} parse(ps : ParseStream) : Exp (* and methods with def *)
9
           (* ... here, there would be code for a pattern syntax parser
10
             generating Wyvern abstract syntax, encoded by the type Exp.
11
             It will be called statically to elaborate Pattern literals (see text) ... *)
12
```

# 3 Extensible Syntax

We begin by considering extensible concrete syntax for languages with a fixed semantics. We will work in context of a simplified variant of a language we are developing called Wyvern, but will emphasize the generality of the approach. The examples given in Sec. 1.1 as well as in this section use Wyvern's syntax.

We observe that many syntax extensions are motivated by the desire to introduce alternative introductory forms (a.k.a. *literal forms*) for a particular type or parameterized type constructor (we will consider the former a degenerate case of the latter for simplicity). For example, regular expression pattern literals as described in Sec. 1.1.1 are introductory syntax for the Pattern type, defined in Wyvern as shown on lines 1-6 of Figure 3. Similarly, list literals, e.g. [1, 2, 3], which are built in to most languages, are introductory syntax for the list type constructor, which is usually included in the standard library.

Specialized syntax like this is often built into a language via an *elaboration*, i.e. by a rewriting from the concrete syntax to an equivalent term that uses general-purpose syntax. For example, [1, 2, 3] might elaborate to Cons(1, Cons(2, Cons(3, Nil))) and the example from bullet point 2(a) in Sec. 1.1.1 might elaborate to the following:

```
let p : Pattern = Seq(Str(fourChars), Seq(Str("-"), twoDigits))
```

We would like to be able to define new syntactic forms together with their elaborations in libraries, but the main problem is that allowing library providers to arbitrarily modify the base syntax of a language could lead to ambiguities when extensions are used together.

**Contribution 3.1** (Tycon-Specific Languages). Our first contribution will be to describe a mechanism that allows new delimited literal forms, defined in terms of an elaboration, to be associated directly with a declared type constructor (i.e. those identified nominally, like datatypes in ML, or classes in Java). We call these *tycon-specific languages (TSLs)*. To prevent syntactic ambiguities, the syntax associated with a tycon is used only when a literal form appears where a term of a type it constructs is expected. For example, the parser elided on lines 10-12 of Figure 3 is invoked statically when parsing the examples in Sec. 1.1.1, only.

Contribution 3.2 (Layout Delimited Literal Forms). Our mechanism relies on a fixed set of delimiters that separate the host language from extensions. For example, we can use curly braces, square brackets, angle brackets and quotation marks equivalently (the choice is merely stylistic). These are sufficient for simple examples like lists and regular expressions, but for specialized syntax that could contain arbitrary characters, e.g. syntax for a type encoding the structure of an HTML document, we could face the same issue discussed in Sec. 1.1.1: syntactic conflict between the delimiter used and the body of the delimited form. To solve this problem, we introduce a *layout-delimited literal form*, shown in Figure 4. We formalize the layout-delimited syntax of Wyvern using an Adams' grammar [5].

**Contribution 3.3** (Formal Semantics of TSLs). We formalize the static semantics, including the literal parsing logic, of TSLs in Wyvern by combining a bidirectional type system [29]

```
let imageBase : URL = <images.example.com>
let bgImage : URL = <%imageBase%/background.png>
3 def resultsFor(searchQuery, page)
     serve(~) (* serve : HTML -> Unit *)
4
5
        >html
6
        >head
          >title Search Results
8
          >style ~
             body { background-image: url(%bgImage%) }
9
            #search { background-color: %darken('#aabbcc', 10pct)% }
10
          >h1 Results for < Text(searchQuery)
         >div[id="search"]
13
           Search again: < SearchBox("Go!")</pre>

Figure 4: Wyvern Example with Multiple TSLs. The tilde indicates a forward referenced literal. Layout determines where it ends. Each type with a TSL is associated with a color for the purposes of our exposition. Black is the base language.

with an elaboration semantics (like the Harper-Stone semantics for Standard ML [17]). By distinguishing locations where an expression synthesizes a type from locations where an expression is being analyzed against a known type, we can precisely state where literal forms can and cannot appear and how parsing is delegated to a TSL. The key judgements are of the form:

```
\Gamma \vdash_{\Theta} e \leadsto i \Leftarrow \tau and \Gamma \vdash_{\Theta} e \leadsto i \Rightarrow \tau
```

External terms, e, elaborate to *internal terms*, i (which do not contain specialized syntax) simultaneously with typechecking. The first judgement captures situations where type analysis is occurring (i.e. there is some type that the term must have), the second type synthesis. Literal syntax can only appear in analytic positions. The typing context,  $\Gamma$ , is standard, and the named type context,  $\Theta$ , associates named types with their declarations and metadata.

**Contribution 3.4** (Formal Semantics of Hygiene). A naïve rewriting strategy would be *unhygienic* – it could allow for the inadvertent capture and shadowing of variables around a literal by the generated code. We will describe a mechanism that ensures hygiene by requiring that the generated AST is closed except for subtrees derived from portions of the user's parse stream that are interpreted as spliced Wyvern expressions or identifiers. We formalize this by separately tracking variables introduced by the desugaring from variables that are in the surrounding context.

**Contribution 3.5** (Empirical Support for Applicability of TSLs and TSMs). To examine how broadly applicable the technique is, we have conducted a simple corpus analysis, finding that statically parseable strings are used ubiquitously in existing Java code.

**Contribution 3.6** (Typed Syntax Macros). For types that are not identified nominally, i.e. arrow types, or types that already have a TSL but would benefit from alternative syntax, we will also design and formalize the semantics of a mechanism for explicitly invoked syntax extensions based on the same underlying techniques. For example, rather than using the alternative HTML syntax defined by the TSL above, we might want to use standard HTML syntax. We could define this as follows:

```
syntax standardHTML => HTML = (* ... parser for standard HTML syntax ... *)
```

It could then be used as a prefix on the same set of delimited forms to change how they are parsed, e.g.

```
standardHTML ~
  <html>...</html>
```

We call explicitly invoked syntax extensions like this *typed syntax macros* (*TSMs*). TSMs can be used as the sole extension mechanism in a language that does not use bidirectional typechecking (e.g. in ML-like languages that use non-local type inference).

**Contribution 3.7** (Syntax for Abstract Types (Design)). For abstract types defined in ML-style modules, we also need some way to associate syntax with them. We can use TSMs for any particular such type, but it would be better to be able to define syntax for all realizations of an abstract type. For example, if we defined sets via a signature SET:

```
signature SET = sig
  type 'a t (* t is an abstract type constructor parameterized by type 'a *)
  val empty : 'a t
  val add : 'a -> 'a t -> 'a t
  val contains : 'a -> 'a t -> bool
```

then we would want to be able to define syntax for the abstract type t defined by any structure (i.e. module) satisfying the SET signature:

```
syntax set(s : SET) => s.t = (* ... parser parameterized by structure s ... *)
```

We would invoke this syntax macro by providing it with a particular structure that satisfies the SET signature, e.g. set[ListSet] {1, 2, 3}. This would suffice for a language like ML.

In a bidirectionally typed language like Wyvern, we could go further by associating such syntax with any particular abstract type, e.g. when defining a structure:

```
structure ListSet : SET = struct
  type 'a t with syntax set = 'a list
...
```

or when defining a functor abstracting over structures:

```
functor MyStructure(S : SET)
  with type S.t with syntax set = struct
```

We could then use the syntax defined for these types like a TSL, without explicitly invoking set[ListSet]. For example:

```
val x : ListSet.t = {1, 2, 3}
```

### 3.1 Timeline

Contribution 3.1 through 3.5 were published at ECOOP 2014 [25]. The only piece that was not described there was support for parameterized type constructors, which we plan to formalize in Spring 2015. Note that this was joint work with several group members, but I was the lead author and led the conceptual aspects of the paper.

Contribution 3.6 is in submission to the ACM Symposium on Applied Computing (notification is Nov. 30). This was joint work with Chenglong Wang, an undergraduate student I worked closely with in Summer 2014.

I have discussed aspects of Contribution 3.7 with Prof. Harper. It will be completed in Spring 2015 (possibly for submission to ICFP in March, or as a part of a journal version of the work above).

### 4 Extensible Semantics

Wyvern has an extensible syntax but a fixed static semantics based around recursive sum and product types. These are simple and highly general but there remain situations where providers may wish to extend the type system of a language directly by introducing new type and operator constructors. Examples of language dialects motivated by a need for this level of control abound in the research literature. For example, to implement the features in Sec. 1.1.2, new logic must be added to the type system to statically track information related to the regular language a string is in, which might involve complex decision procedures for language inclusion [15]. Labeled products as described in Sec. 1.1.3 similarly cannot be defined as libraries, because the projection and functional update operators would not have function type.

We seek to enable the introduction of new type and operator constructors like these in a manner that makes it possible to reason about their metatheory once, in a "closed world" setting. We would then rely on a more general principle to be sure that this reasoning is conserved in the "open world". For example, once a language is extended with regular string types as described in Sec. 1.1.2 (which Nathan Fulton and I specified in [15]), all terms having a regular string type like  $RSTR\langle/.+/\rangle$  should continue to behave as nonempty strings no matter which other extensions are in use. The extension defining labeled products should not be able to "sneak in" a value of this regular string type that does not obey this invariant.

**Contribution 4.1** (Modular Type Constructors). We propose constructing a typed translation semantics,  $@\lambda$ , where new type constructors and their associated operator constructors can be introduced modularly.

### 4.1 Overview of $@\lambda$

**Internal Language** At the heart of our semantics is a typed internal language supporting type abstraction (i.e. universal quantification over types) [31]. We use  $\mathcal{L}\{ \to \forall \mu 1 \times + \}$ , Figure 5, as representative of a typical intermediate language for a typed language. We assume an internal statics specified by judgements for type assignment  $\Delta \Gamma \vdash \iota : \tau^+$ , type formation  $\Delta \vdash \tau$  and typing context formation  $\Delta \vdash \Gamma$ , and an internal dynamics specified as a structural operational semantics with a stepping judgement  $\iota \mapsto \iota^+$  and a value judgement  $\iota$  val.<sup>2</sup> Both the static and dynamic semantics of the IL can be found in any standard textbook covering typed lambda calculi (e.g. [16] or [28]).

**External Language** Programs "execute" as internal terms, but programmers interface with @ $\lambda$  by writing *external terms*, e. The abstract syntax of external terms is shown in Figure 6 and we introduce various concrete desugarings as we go on. The semantics are specified as a *bidirectionally typed translation semantics*, i.e. the key judgements have the following form, pronounced "under typing context  $\Upsilon$  and tycon context  $\Phi$ , e (synthesizes / analyzes against) type  $\sigma$  and has translation  $\iota$ ":

$$\Upsilon \vdash_{\Phi} e \Rightarrow \sigma^+ \leadsto \iota^+ \quad \text{and} \quad \Upsilon \vdash_{\Phi} e \Leftarrow \sigma \leadsto \iota^+$$

We distinguish situations where the type is an "output" from those where it must be provided as an "'input" using such a bidirectional approach, also known as *local type inference* [29], for two reasons. The first is to justify the practicality of our approach: local type inference is increasingly being used in contemporary languages (e.g. Scala [24]) because it eliminates the need for type annotations in many places and provides high quality error messages. Secondly, it will give us a clean way to reuse the abstract introductory form,  $intro[\sigma](\bar{e})$ , and its associated desugarings, at many types.

 $<sup>^2</sup>$ Our specifications are intended to be algorithmic: we indicate "outputs" when introducing judgement forms by *mode annotations*,  $^+$ .

# $\begin{array}{lll} \textbf{internal types} \\ \tau & ::= & \tau \rightharpoonup \tau \mid \alpha \mid \forall (\alpha.\tau) \mid t \mid \mu(t.\tau) \mid \mathbf{1} \mid \tau \times \tau \mid \tau + \tau \\ \textbf{internal terms} \\ \iota & ::= & x \mid \lambda x : \tau.\iota \mid \iota(\iota) \mid \mathsf{fix}[\tau](x.\iota) \mid \Lambda(\alpha.\iota) \mid \iota[\tau] \\ & \mid & \mathsf{fold}[t.\tau](\iota) \mid \mathsf{unfold}(\iota) \mid () \mid (\iota,\iota) \mid \mathsf{fst}(\iota) \mid \mathsf{snd}(\iota) \\ & \mid & \mathsf{inl}[\tau](\iota) \mid \mathsf{inr}[\tau](\iota) \mid \mathsf{case}(\iota; x.\iota; x.\iota) \\ \textbf{internal typing contexts} \; \Gamma ::= \emptyset \mid \Gamma, x : \tau \\ \textbf{internal type formation contexts} \; \Delta ::= \emptyset \mid \Delta, \alpha \mid \Delta, t \\ \end{array}$

Figure 5: Syntax of  $\mathcal{L}\{ \rightharpoonup \forall \mu \ 1 \times + \}$ , our internal language (IL). Metavariable x ranges over term variables and  $\alpha$  and t (distinguished only for stylistic reasons) over type variables.

```
\begin{array}{ll} \textbf{external terms} \\ e & ::= & x \mid \lambda x.e \mid \lambda x.\sigma.e \mid e(e) \mid \mathsf{fix}(x.e) \mid e : \sigma \\ & \mid & \mathsf{intro}[\sigma](\overline{e}) \mid \mathsf{targop}[\mathsf{op};\sigma](e;\overline{e}) \\ \textbf{argument lists } \overline{e} ::= \cdot \mid \overline{e}; e \\ \textbf{external typing contexts } \Upsilon ::= \emptyset \mid \Upsilon, x : \sigma \end{array}
```

Figure 6: Abstract syntax of the external language (EL).

**Main Example** For example, consider the following types:

The regular string types  $\sigma_{\text{title}}$  and  $\sigma_{\text{conf}}$  classify values that behave as strings known to be in a specified regular language [15], i.e.  $\sigma_{\text{title}}$  classifies non-empty strings and  $\sigma_{\text{conf}}$  classifies strings having the format of a typical conference name. The *labeled product type*  $\sigma_{\text{paper}}$  then describes a conference paper by defining two *rows*, each having one of the regular string types just described. Neither tycons are built in – regular string types are defined in tycon context  $\Phi_{\text{rstr}}$  and labeled products in  $\Phi_{\text{lprod}}$ , both introduced in Sec. 4.2.

We next define a function,  $e_{\rm ex}$ , that takes a paper title and produces a paper in a conference named "EXMPL 2015":

```
\begin{array}{lll} e_{\rm ex} & := & \lambda title{:}\sigma_{\rm title}{:}e_{\rm paper}{:}\sigma_{\rm paper} \\ e_{\rm paper} & := & \{{\tt title}{=}title, {\tt conf}{=}"{\tt EXMPL}~{\tt 2015"}\} \end{array}
```

We will detail the syntax and semantics in Sec. 4.3, but to briefly summarize: because of the type ascription  $\sigma_{\text{paper}}$ , semantic control over  $e_{\text{paper}}$  will be delegated to the *intro opcon* defined by LPROD. It will decide to analyze the the row value of title against  $\sigma_{\text{title}}$  and the row value of conf, a string literal, against  $\sigma_{\text{conf}}$ , causing control to pass similarly to RSTR. Satisfied that the term is well-typed, these opcons will generate translations, which will pass through our validation procedure (described below). We will ultimately derive:

$$\emptyset \vdash_{\Phi_{\text{rstr}}\Phi_{\text{lprod}}} e_{\text{ex}} \Rightarrow (\sigma_{\text{title}} \rightharpoonup \sigma_{\text{paper}}) \leadsto \iota_{\text{ex}}$$

where  $\iota_{\mathrm{ex}}:=\lambda title$ :str. $(title,("EXMPL 2015"_{\mathrm{IL}},()))$ . Note that labels were erased, and "EXMPL 2015" $_{\mathrm{IL}}$  is an internal string (of internal type str, defined suitably). The trailing unit value arises only because it simplifies our exposition.

The type annotation on the internal function could be determined because types also have translations, specified by the *type translation judgement*  $\vdash_{\Phi} \sigma$  type  $\leadsto \tau^+$ , read " $\sigma$  is a type under  $\Phi$  with translation  $\tau$ ". For example,  $\sigma_{\text{title}}$  and  $\sigma_{\text{conf}}$  have type translations str and  $\sigma_{\text{paper}}$  in turn has str  $\times$  (str  $\times$  1).

Selectively holding type translations abstract will be the key to modular metatheoretic reasoning. For example, LPROD cannot claim that a row has a regular string type but produce a translation inconsistent with this claim, e.g. the translation  $(""_{IL}, ("EXMPL"_{IL}, ()))$ 

```
kinds \kappa \quad ::= \quad \kappa \to \kappa \mid \alpha \mid \forall (\alpha.\kappa) \mid k \mid \mu_{\mathrm{ind}}(k.\kappa) \mid 1 \mid \kappa \times \kappa \mid \kappa + \kappa \mid \kappa + \kappa \mid \tau \mid \tau \mid |\mathsf{Ty} \mid \mathsf{Tm} static terms \sigma \quad ::= \quad x \mid \lambda x :: \kappa.\sigma \mid \sigma(\sigma) \mid \cdots \mid \mathsf{raise}[\kappa] \mid \quad c\langle \sigma \rangle \mid \mathsf{tycase}[c](\sigma; x.\sigma; \sigma) \mid \quad \blacktriangleright (\hat{\tau}) \mid \rhd (\hat{\iota}) \mid \mathsf{ana}[n](\sigma) \mid \mathsf{syn}[n] translational internal types and terms \hat{\tau} \quad ::= \quad \blacktriangleleft (\sigma) \mid \mathsf{trans}(\sigma) \mid \hat{\tau} \rightharpoonup \hat{\tau} \mid \ldots \\ \hat{\iota} \quad ::= \quad \lhd (\sigma) \mid \mathsf{anatrans}[n](\sigma) \mid \mathsf{syntrans}[n] \mid x \mid \lambda x : \hat{\tau}.\hat{\iota} \mid \ldots  kinding contexts \Gamma ::= \quad \emptyset \mid \Gamma, x :: \kappa \mid \kappa \mid \Gamma, x :: \kappa \mid \Gamma, x ::
```

Figure 7: Syntax of the static language (SL). Metavariables x ranges over static term variables,  $\alpha$  and k over kind variables and n over natural numbers.

is invalid for a term of type  $\sigma_{paper}$ , despite being of internal type  $\operatorname{str} \times (\operatorname{str} \times 1)$ . The reason is that it will be validated against  $\alpha_1 \times (\alpha_2 \times 1)$ , i.e. with all type translations of regular string types held abstract. This is, encouragingly, the same fundamental principle underlying representation independence in ML-style module systems. As in ML, mechanized specifications and proofs are not needed.

**Static Language** As suggested above, the main novelty of @ $\lambda$  is that the types and term and type translations do not arise from a fixed specification. Rather, they are *statically computed* by tycon definitions using a *static language* (SL). The SL is itself a typed lambda calculus where *kinds*,  $\kappa$ , serve as the "types" of *static terms*,  $\sigma$ . Its syntax is shown in Figure 7. The portion of the SL covered by the first row of kinds and static terms, some of which are elided, forms a standard functional language consisting of total functions, polymorphic and inductive kinds, and products and sums [16]. It can be seen as a total subset of ML.

Only three new kinds are needed for the SL to serve its role: 1) Ty, classifying types (Sec. 4.2); 2) ITy, classifying *quoted translational internal types*, used to compute type translations in Sec. 4.2.4; and (3) ITm, classifying *quoted translational internal terms*, used to compute term translations in Sec. 4.3.1. The forms  $\operatorname{ana}[n](\sigma)$  and  $\operatorname{syn}[n]$  will allow tycon definitions to request analysis or synthesis of operator arguments, linking the SL with the EL.

The kinding judgement takes the form  $\Delta \Gamma \vdash_{\Phi}^n \sigma :: \kappa^+$ , where  $\Delta$  and  $\Gamma$  are analogous to  $\Delta$  and  $\Gamma$  and analogous judgements  $\Delta \vdash \kappa$  and  $\Delta \vdash \Gamma$  are defined. The natural number n is simply a bound used to prevent "out of bounds" references to arguments. The computational behavior of static terms (i.e. the *static dynamics*) is defined by a stepping judgement  $\sigma \mapsto_{\mathcal{A}} \sigma^+$ , a value judgement  $\sigma$  val $_{\mathcal{A}}$  and an *error raised* judgement  $\sigma$  err $_{\mathcal{A}}$ . A ranges over *argument environments*, which we return to in Sec. 4.3.2. The multi-step judgement  $\sigma \mapsto_{\mathcal{A}}^* \sigma^+$  is the reflexive, transitive closure of the stepping judgement and the normalization judgement  $\sigma \Downarrow_{\mathcal{A}} \sigma'$  is derivable iff  $\sigma \mapsto_{\mathcal{A}}^* \sigma'$  and  $\sigma'$  val $_{\mathcal{A}}$ .

### 4.2 Types

Types are static values of kind Ty, i.e. we write  $\sigma$  type $_{\Phi}$  iff  $\sigma$  val $_{\mathcal{A}}$  and  $\emptyset \emptyset \vdash_{\Phi}^{n} \sigma ::$  Ty. All types are of the form  $c\langle \sigma \rangle$ , where c is a *tycon* and  $\sigma$  is the *type index*. Three kinding rules govern this form, shown in Figure 8, one for each of the three forms for tycons given in Figure 9. The dynamics are simple: the index is eagerly normalized and errors propagate.<sup>3</sup>

**Function Types** In our example, we assumed a desugaring from  $\sigma_1 \rightharpoonup \sigma_2$  to  $\rightharpoonup \langle (\sigma_1, \sigma_2) \rangle$ . The rule (k-ty-parr) specifies that the type index of partial function types must be a pair of types. We thus say that  $\rightharpoonup$  has *index kind* Ty  $\times$  Ty.

<sup>&</sup>lt;sup>3</sup>The full rules are provided in a detailed supplement, which is available upon request.

Figure 8: Kinding rules for types.

**Extension Types** For types constructed by an *extension tycon*, written TC, rule (k-ty-ext) checks for a *tycon definition* for TC in the tycon context,  $\Phi$ . The syntax of tycon contexts is shown in Figure 9 and our main examples are in Figure 10. For now, the only relevant detail is that each tycon defines a *tycon signature*,  $\psi$ , which in turn defines the index kind used in the second premise of (k-ty-ext).

Types constructed by RSTR, e.g.  $\sigma_{\rm title}$  and  $\sigma_{\rm conf}$ , specify regular expressions as their indices. The tycon signature of RSTR,  $\psi_{\rm rstr}$  in Figure 10, thus specifies index kind Rx, which classifies static regular expression patterns (defined as an inductive sum kind in the usual way). We wrote the type indices in our example assuming a standard concrete syntax. Recent work has shown how to define such type-specific, or here kind-specific, syntax composably [25].

Under the composed context  $\Phi_{rstr}\Phi_{lprod}$ , we defined the labeled product type  $\sigma_{paper}$ . The index kind of LPROD, given by  $\psi_{lprod}$  in Figure 10, is List[Lbl  $\times$  Ty], where list kinds are defined in the usual way, and Lbl classifies static representations of row labels, and we again used kind-specific syntax to approximate a conventional syntax for row specifications.

**Other Types** Rule (k-ty-other) governs types constructed by a tycon of the form other  $[m; \kappa]$ . These will serve only as technical devices to stand in for tycons other than those in a given tycon context in Theorem 5. The natural number m serves to ensure there are arbitrarily many of these tycons. The index pairs any value of *equality kind*  $\kappa$ , discussed in Sec. 4.2.3, with a value of kind ITy, discussed in Sec. 4.2.4.

### 4.2.1 Type Case Analysis

Types might be thought of as arising from a distinguished "open datatype" [20] defined by the tycon context. Consistent with this view, a type  $\sigma$  can be case analyzed using tycase[c]( $\sigma$ ;x. $\sigma$ <sub>1</sub>; $\sigma$ <sub>2</sub>). If the value of  $\sigma$  is constructed by c, its type index is bound to x and branch  $\sigma$ <sub>1</sub> is taken. For totality, a default branch,  $\sigma$ <sub>2</sub>, must be provided. For example, the kinding rule for extension tycons is:

We will see an example of its use in an opcon definition in Sec. 4.3.4. The rule for  $c=\rightharpoonup$  is analogous, but, importantly, no rule for c= other $[m;\kappa]$  is defined (these types always take the default branch and their indices cannot be examined).

### 4.2.2 Tycon Contexts

The tycon context well-definedness judgement,  $\vdash \Phi$  is given in Figure 11 (omitting the trivial rule for  $\Phi = \cdot$ ).

```
\begin{array}{ccccc} \text{tycons} & c & ::= & \rightharpoonup \mid \mathsf{TC} \mid \mathsf{other}[m;\kappa] \\ \text{tycon contexts} & \Phi & ::= & \cdot \mid \Phi, \mathsf{tycon} \ \mathsf{TC} \ \{\theta\} \sim \psi \\ \text{tycon structures} & \theta & ::= & \mathsf{trans} = \sigma \ \mathsf{in} \ \omega \\ \text{opcon structures} & \omega & ::= & \mathsf{ana} \ \mathsf{intro} = \sigma \mid \omega; \mathsf{syn} \ \mathsf{op} = \sigma \\ \text{tycon sigs} & \psi & ::= & \mathsf{tcsig}[\kappa] \ \{\chi\} \\ \text{opcon sigs} & \chi & ::= & \mathsf{intro}[\kappa] \ \mid \chi; \mathsf{op}[\kappa] \end{array}
```

Figure 9: Syntax of tycons. Metavariables TC, **op** and m range over extension tycon and opcon names and natural numbers, respectively. We omit leading  $\cdot$  in examples.

```
\psi_{rstr} := tcsig[Rx] \{intro[Str]; conc[1]; case[StrPattern]; ... \}
\psi_{lprod} := \mathsf{tcsig}[\mathsf{List}[\mathsf{Lbl} \times \mathsf{Ty}]] \left\{ \mathsf{intro}[\mathsf{List}[\mathsf{Lbl}]]; \#[\mathsf{Lbl}]; \mathbf{conc}[1]; ... \right\}
                                                   \Phi_{lprod} := \mathsf{tycon}\; \mathsf{LPROD}\; \{
\Phi_{\rm rstr} := {\sf tycon} \ {\sf RSTR} \ \{
                                               trans = \sigma_{\rm lprod/schema} in
   \mathsf{trans} = \sigma_{\mathsf{rstr/schema}} in
                                                                                                  (Sec 4.2.4)
                                                    ana intro = \sigma_{lprod/intro}; (Sec 4.3.1)
   ana intro = \sigma_{
m rstr/intro};
   \mathsf{syn}\; \mathbf{conc} = \sigma_{\mathsf{rstr/conc}};
                                                                                                   (Sec 4.3.4)
                                                    syn # = \sigma_{lprod/prj};
                                                      syn conc = \sigma_{lprod/conc}; (Sec 4.3.4)
   syn case = \sigma_{\rm rstr/case};
    \cdots \} \sim \psi_{\rm rstr}
                                                      \cdots \} \sim \psi_{\mathsf{lprod}}
```

Figure 10: Example tycon signatures and definitions.

### 4.2.3 Type Equivalence

The first of the three checks in (tcc-ext), and the check in (k-ty-other), simplifies type equivalence: type index kinds must be *equality kinds*, i.e. those for which semantically equivalent values are syntactically equal. Equality kinds are defined by the judgement  $\Delta \vdash \kappa$  eq (see supplement) and are exactly analogous to equality types as in Standard ML [21]. Arrow kinds are not equality kinds.

### 4.2.4 Type Translations

Recall that a type,  $\sigma$ , defines a translation,  $\tau$ . Extension tycons compute translations for the types they construct as a function of each type's index by specifying a *translation schema* in the tycon structure,  $\theta$ . The translation schema must have kind  $\kappa_{\rm tyidx} \to {\sf ITy}$ , checked by the third premise of (tcc-ext). Terms of kind ITy are introduced by a *quotation form*,  $\blacktriangleright(\hat{\tau})$ , where  $\hat{\tau}$  is a *translational internal type*. Each form of internal type,  $\tau$ , has a corresponding form of translational internal type. For example, regular string types have type translations abbreviated str. Abbreviating the corresponding translational internal type str, we define the translation schema of RSTR as  $\sigma_{\rm rstr/trans} := \lambda tyidx::Rx. \blacktriangleright(\hat{\it str})$ .

The syntax for  $\hat{\tau}$  also includes an "unquote" form,  $\blacktriangleleft(\sigma)$ , so that they can be constructed compositionally, as well as a form, trans( $\sigma$ ), that refers to another type's translation. These have the following simple kinding rules:

The semantics for the shared forms propagates the quotation marker recursively to ensure these are reached, e.g.

$$\frac{\text{(k-ity-prod)}}{\Delta \; \Gamma \vdash_{\Phi}^{n} \blacktriangleright (\hat{\tau}_{1}) :: \mathsf{ITy}} \quad \frac{\Delta \; \Gamma \vdash_{\Phi}^{n} \blacktriangleright (\hat{\tau}_{2}) :: \mathsf{ITy}}{\Delta \; \Gamma \vdash_{\Phi}^{n} \blacktriangleright (\hat{\tau}_{1} \times \hat{\tau}_{2}) :: \mathsf{ITy}}$$

These are needed in the translation schema for LPROD, which generates nested binary product types by folding over the type index and referring to the translations of the types

```
\begin{split} & (\text{tcc-ext}) \\ & \vdash \Phi \quad \emptyset \vdash \kappa_{\text{tyidx}} \text{ eq } \quad \emptyset \not \models \bigoplus_{\Phi}^{0} \sigma_{\text{schema}} :: \kappa_{\text{tyidx}} \to \mathsf{ITy} \\ & \vdash_{\Phi, \text{tycon TC }} \{_{\text{trans} = \sigma_{\text{schema}}} \text{ in } \omega \} \sim \mathsf{tcsig}[\kappa_{\text{tyidx}}] \{\chi\} \\ & \vdash \Phi, \text{tycon TC } \{_{\text{trans}} = \sigma_{\text{schema}} \text{ in } \omega\} \sim \mathsf{tcsig}[\kappa_{\text{tyidx}}] \{\chi\} \end{split}
```

Figure 11: Tycon context well-definedness.

therein. We assume the standard *fold* function in defining:

```
\begin{split} \sigma_{\mathrm{lprod/trans}} &:= \lambda tyidx :: \mathsf{List}[\mathsf{Lbl} \times \mathsf{Ty}]. \textit{fold tyidx} \blacktriangleright (1) \\ & (\lambda h : \mathsf{Lbl} \times \mathsf{Ty}. \lambda r : \mathsf{lTy}. \blacktriangleright (\mathsf{trans}(\mathsf{snd}(h)) \times \blacktriangleleft (r)) \end{split}
```

Applying this translation schema to the index of  $\sigma_{paper}$ , for example, produces the value  $\sigma_{paper/trans} := \blacktriangleright(\hat{\tau}_{paper/trans})$  where  $\hat{\tau}_{paper/trans} := \operatorname{trans}(\sigma_{title}) \times (\operatorname{trans}(\sigma_{conf}) \times 1)$ . Note that references to translations of types are retained in values of kind ITy, while unquote forms are eliminated (see supplement for the full semantics of quotations).

### 4.2.5 Selective Type Translation Abstraction

References to type translations are maintained in values like this to allow us to selectively hold them abstract. This can be thought of as analagous to the process in ML by which the true identity of an abstract type in a module is held abstract outside the module until after typechecking. The judgement  $\hat{\tau} \parallel \mathcal{D} \hookrightarrow_{\Phi}^c \tau^+ \parallel \mathcal{D}^+$  relates a normalized translational internal type  $\hat{\tau}$  to an internal type  $\tau$ , called a *selectively abstracted type translation* because references to translations of types *constructed by a tycon other than the delegated tycon, c,* are replaced by a corresponding type variable,  $\alpha$ . For example,  $\hat{\tau}_{paper/trans} \parallel \emptyset \hookrightarrow_{\Phi_{rstr}\Phi_{lprod}}^{LPROD} \tau_{paper/abs} \parallel \mathcal{D}_{paper/abs}$  where  $\tau_{paper/abs} := \alpha_1 \times (\alpha_2 \times 1)$ .

The type translation store  $\mathcal{D} := \emptyset \mid \mathcal{D}, \sigma \leftrightarrow \tau/\alpha$  maintains the correspondence between types, their actual translations and the distinct type variables appearing in their place, e.g.  $\mathcal{D}_{paper/abs} := \sigma_{title} \leftrightarrow \mathsf{str}/\alpha_1, \sigma_{\mathsf{conf}} \leftrightarrow \mathsf{str}/\alpha_2$ . The judgement  $\mathcal{D} \leadsto \delta^+ : \Delta^+$  constructs the n-ary type substitution,  $\delta := \emptyset \mid \delta, \tau/\alpha$ , and corresponding internal type formation context,  $\Delta$ , implied by the type translation store  $\mathcal{D}$ . For example,  $\mathcal{D}_{paper/abs} \leadsto \delta_{paper/abs} : \Delta_{paper/abs}$  where  $\delta_{paper/abs} := \mathsf{str}/\alpha_1, \mathsf{str}/\alpha_2$  and  $\Delta_{paper/abs} := \alpha_1, \alpha_2$ .

We can apply type substitutions to internal types, terms and typing contexts, written  $[\delta]\tau$ ,  $[\delta]\iota$  and  $[\delta]\Gamma$ , respectively. For example,  $[\delta_{paper/abs}]\tau_{paper/abs}$  is  $\tau_{paper}:= \operatorname{str} \times (\operatorname{str} \times 1)$ , i.e. the actual type translation of  $\sigma_{paper}$ . Indeed, we can now define the type translation judgement,  $\vdash_{\Phi} \sigma$  type  $\leadsto \tau$ , mentioned in Sec. 4.1. We simply determine any selectively abstracted translation, then apply the implied substitution:

$$\frac{\sigma \; \mathsf{type}_{\Phi} \qquad \mathsf{trans}(\sigma) \parallel \emptyset \hookrightarrow^{c}_{\Phi} \tau \parallel \mathcal{D} \qquad \mathcal{D} \leadsto \delta : \Delta}{\vdash_{\Phi} \sigma \; \mathsf{type} \leadsto [\delta] \tau}$$

The rules for the selective type translation abstraction judgement recurse generically over shared forms in  $\hat{\tau}$ . Only sub-terms of form  $\operatorname{trans}(\sigma)$  are interesting. The translation of an extension type is determined by calling the translation schema and validating that the type translation it generates is closed except for type variables tracked by  $\mathcal{D}'$ . If constructed by the delegated tycon, it is not held abstract:

$$\begin{split} & \text{(abs-ext-delegated)} \\ & \text{tycon TC } \{ \text{trans} = \sigma_{\text{schema}} \text{ in } \omega \} \sim \psi \in \Phi \quad \quad \sigma_{\text{schema}}(\sigma_{\text{tyidx}}) \Downarrow_{:;\emptyset;\Phi} \blacktriangleright (\hat{\tau}) \\ & \frac{\hat{\tau} \parallel \mathcal{D} \looparrowright_{\Phi}^{\text{TC}} \tau \parallel \mathcal{D}' \quad \quad \mathcal{D}' \leadsto \delta : \Delta \quad \quad \Delta \vdash \tau }{\text{trans}(\text{TC}\langle \sigma_{\text{tyidx}} \rangle) \parallel \mathcal{D} \looparrowright_{\Phi}^{\text{TC}} \tau \parallel \mathcal{D}'} \end{split}$$

Otherwise, it is held abstract via a fresh type variable added to the store (the supplement

gives rule (abs-ty-stored) for retrieving it if already there):

```
 \begin{split} & (\text{abs-ext-not-delegated-new}) \\ & c \neq \text{TC} & & \text{TC}\langle\sigma_{\text{tyidx}}\rangle \notin \text{dom}(\mathcal{D}) & \text{tycon TC } \{\text{trans} = \sigma_{\text{schema}} \text{ in } \omega\} \sim \psi \in \Phi \\ & & \sigma_{\text{schema}}(\sigma_{\text{tyidx}}) \Downarrow_{\cdot;\emptyset;\Phi} \blacktriangleright (\hat{\tau}) & \hat{\tau} \parallel \mathcal{D} \hookrightarrow_{\Phi}^{c} \tau \parallel \mathcal{D}' \\ & & \mathcal{D}' \leadsto \delta : \Delta & \Delta \vdash \tau & (\alpha \text{ fresh}) \\ & & & \text{trans}(\text{TC}\langle\sigma_{\text{tyidx}}\rangle) \parallel \mathcal{D} \hookrightarrow_{\Phi}^{c} \alpha \parallel \mathcal{D}', \text{TC}\langle\sigma_{\text{tyidx}}\rangle \leftrightarrow [\delta]\tau/\alpha \end{split}
```

The translations of "other" types are given directly in their indices (in Sec. 4.4, we will replace some extension types with other types, and this is how we preserve their translations):

$$\begin{split} & \text{(abs-other-delegated)} \\ & \frac{\hat{\tau} \parallel \mathcal{D} \ominus^{\text{other}[m;\kappa]}_{\Phi} \tau \parallel \mathcal{D}' \quad \mathcal{D}' \leadsto \delta : \Delta \quad \Delta \vdash \tau}{\text{trans}(\text{other}[m;\kappa] \langle (\sigma, \blacktriangleright(\hat{\tau}) \rangle) \parallel \mathcal{D} \ominus^{\text{other}[m;\kappa]}_{\Phi} \tau \parallel \mathcal{D}'} \end{split}$$

Rule (abs-other-not-delegated-new) is analogous to (abs-ext-not-delegated-new), and is shown in the supplement.

The translations of function types are not held abstract, so that lambdas, which are built in, can be the sole binding construct in the EL:

$$\frac{\mathsf{trans}(\sigma_1) \parallel \mathcal{D} \hookrightarrow_{\Phi}^c \tau_1 \parallel \mathcal{D}' \qquad \mathsf{trans}(\sigma_2) \parallel \mathcal{D}' \hookrightarrow_{\Phi}^c \tau_2 \parallel \mathcal{D}''}{\mathsf{trans}(\neg \langle (\sigma_1, \sigma_2) \rangle) \parallel \mathcal{D} \hookrightarrow_{\Phi}^c \tau_1 \rightharpoonup \tau_2 \parallel \mathcal{D}''}$$

### 4.3 External Terms

Now that we have established how types are constructed and how type translations are computed, we are ready to give the semantics for external terms, shown in Figure 12.

Because we are defining a bidirectional type system, the rule (subsume) is needed to allow synthetic terms to be analyzed against an equivalent type. Per Sec. 4.2.3, equivalent types must be syntactically identical at normal form, and we consider analysis only if  $\sigma$  type $_{\Phi}$ , so the rule is straightforward. To use an analytic term in a synthetic position, the programmer must provide a type ascription, written  $e:\sigma$ . The ascription is kind checked and normalized to a type before being used for analysis by rule (ascribe).

Rules (syn-var) states that variables synthesize types, as is standard. Functions operate in the standard manner given our definitions of types and type translations (used to generate annotations in the IL). We use Plotkin's fixpoint operator for general recursion (cf. [16]), and define it only analytically with rule (ana-fix). We also define an analytic form of lambda without a type ascription to emphasize that bidirectional typing allows you to omit type ascriptions in analytic positions.

### 4.3.1 Generalized Intro Operations

The meaning of the *generalized intro operation*, written  $intro[\sigma_{tmidx}](\overline{e})$ , is determined by the tycon of the type it is being analyzed against as a function of the type's index, the *term index*,  $\sigma_{tmidx}$ , and the *argument list*,  $\overline{e}$ .

Before discussing rules (ana-intro) and (ana-intro-other), we note that we can recover a variety of standard concrete introductory forms by desugaring. For example, the string literal form, "s", desugars to  $\mathsf{intro}["\mathsf{s"}_{\mathsf{SL}}](\cdot)$ , i.e. the term index is the corresponding static value of kind Str and there are no arguments. Similarly, we define a generalized labeled collection form,  $\{\mathsf{lbl}_1 = e_1, \ldots, \mathsf{lbl}_n = e_n\}$ , that desugars to  $\mathsf{intro}[[\mathsf{lbl}_1, \ldots, \mathsf{lbl}_n]](e_1; \ldots; e_n)$ , i.e. a static list constructed from the row labels is the term index and the corresponding row values are the arguments. Additional desugarings are discussed in the supplement. The literal form in  $e_{\mathsf{paper}}$ , from Sec. 4.1, for example, desugars to  $e_{\mathsf{paper}} := \mathsf{intro}[[\mathsf{title}, \mathsf{conf}]](title; \mathsf{intro}["\mathsf{EXMPL} \ 2015"_{\mathsf{SL}}](\cdot))$ .

$$\begin{array}{c} (\text{subsume}) \\ (\text{subsume}) \\ (\text{T} \vdash_{\Phi} e \Rightarrow \sigma \leadsto \iota) \\ (\text{Cana-link}) \\ (\text{Cana-link}) \\ (\text{Cana-link}) \\ (\text{Cana-link}) \\ (\text{Cana-link}) \\ (\text{Syn-lam}) \\ (\text{Syn-lam}) \\ (\text{Syn-lam}) \\ (\text{Syn-lam}) \\ (\text{Syn-lam}) \\ (\text{Syn-lam}) \\ (\text{Cana-intro}) \\ (\text{Syn-lam}) \\ (\text{Cana-intro}) \\ (\text{T} \vdash_{\Phi} e \Rightarrow \sigma \bowtie \sigma \bowtie \iota) \\ (\text{Cana-intro}) \\ (\text{T} \vdash_{\Phi} e \Rightarrow \sigma \bowtie \sigma \bowtie \iota) \\ (\text{Cana-intro}) \\ (\text{Syn-lam}) \\ (\text{Cana-intro}) \\ (\text{Syn-lam}) \\ (\text{Cana-intro}) \\ (\text{Syn-lam}) \\ (\text{Cana-intro}) \\ (\text{Cana-in$$

Figure 13: Opcon structure kinding against tycon signatures

 $\vdash_{\Phi} \omega; \mathsf{syn} \; \mathbf{op} = \sigma_{\mathsf{def}} \sim \mathsf{tcsig}[\kappa_{\mathsf{tyidx}}] \left\{ \chi, \mathbf{op}[\kappa_{\mathsf{tmidx}}] \right\}$

```
\begin{split} \lambda tyidx : & \text{List}[\mathsf{Lbl} \times \mathsf{Ty}]. \lambda tmidx : \mathsf{List}[\mathsf{Lbl}]. \lambda args : \mathsf{List}[\mathsf{Arg}]. \\ & \text{let } inhabited : 1 = uniqmap \ tyidx \ \text{in} \\ & fold3 \ tyidx \ tmidx \ args \rhd(()) \\ & \lambda rowtyidx : \mathsf{Lbl} \times \mathsf{Ty}. \lambda rowtmidx : \mathsf{Lbl}. \lambda rowarg : \mathsf{Arg}. \lambda r : \mathsf{ITm}. \\ & \text{letpair} \ (rowlbl, rowty) = rowtyidx \ \text{in} \\ & \text{let} \ lok :: 1 = lbleq \ rowlbl \ rowtmidx \ \text{in} \\ & \text{let} \ rowtr :: \mathsf{ITm} = ana \ rowarg \ rowty \ \text{in} \\ & \rhd((\lhd(rowtr), \lhd(r))) \end{split}
```

Figure 15: The intro opcon definition for LPROD,  $\sigma_{\rm lprod/intro}$ .

Let us now derive the typing judgement in Sec. 4.1. We first apply (syn-lam), which will ask  $(e_{paper}: \sigma_{paper})$  to synthesize a type in the typing context  $\Upsilon_{ex} = title: \sigma_{title}$ . Then (ascribe) will analyze  $e_{paper}$  against  $\sigma_{paper}$  via (ana-intro).

The first premise of (ana-intro) simply finds the tycon definition for the tycon of the type provided for analysis, in this case LPROD. The second premise extracts the *intro term index kind*,  $\kappa_{\rm tmidx}$ , from the *opcon signature*,  $\chi$ , it specifies. This is simply the kind of term index expected by the tycon, e.g. in Figure 10, LPROD specifies List[Lbl], so that it can use the labeled collection form, while RSTR specifies Str, so that it can use the string literal form. The third premise checks the provided term index against this kind.

The fourth premise extracts the *intro opcon definition* from the *opcon structure*,  $\omega$ , of the tycon structure, calling it  $\sigma_{\text{def}}$ . This is a static function that is applied, in the seventh premise, to determine whether the term is well-typed, raising an error if not or computing a translation if so. Its kind is checked by the judgement  $\vdash_{\Phi} \omega \sim \psi$ , which was the final premise of the rule (tcc-ext) and is defined in Figure 13. Rule (ocstruct-intro) specifies that it has access to the type index, the term index and an interface to the list of arguments, discussed below, and returns a *quoted translational internal term* of kind ITm, analagous to ITy. The intro opcon definitions for RSTR and LPROD are given in Figures 14 and 15.

Though the latter will be encountered first in our example derivation, let us first consider the intro opcon definition in Figure 14 because it is more straightforward. It will be used to analyze the row value intro["EXMPL 2015" $_{SL}$ ](·) against  $\sigma_{conf}$ . It begins by making sure that no arguments were passed in using the helper function arity0:: List[Arg]  $\rightarrow$  1 defined such that any non-empty list will raise an error, via the static term raise[1]. In practice, the tycon provider would specify an error message here. Next, it checks the string provided as the term index against the regular expression given as the type index using rmatch:: Rx  $\rightarrow$  Str  $\rightarrow$  1, which we assume is defined in the usual way and again raises an error on failure. Finally, the translational internal string corresponding to the static string provided as the term index is generated via the helper function  $str_of_Str$ :: Str  $\rightarrow$  ITm.

Static terms of kind ITm are introduceed by the quotation form,  $\triangleright(\hat{\imath})$ , where  $\hat{\imath}$  is a *translational internal term*. This is analogous to the form  $\blacktriangleright(\hat{\tau})$  for ITy in Sec. 4.2.4. Each form in the syntax of  $\imath$  has a corresponding form in the syntax for  $\hat{\imath}$  and the kinding rules and dynamics simply recurse through these in the same manner as in Sec. 4.2.4. There is also an analogous unquote form,  $\triangleleft(\sigma)$ . The two interesting forms of translational internal term are anatrans $[n](\sigma)$  and syntrans[n]. These stand in for the translation of argument n, the first if it arises via analysis against type  $\sigma$  and the second if it arises via type synthesis. Before giving the rules, let us motivate the mechanism with the intro opcon definition for LPROD, shown in Figure 15.

The first line checks that the type provided is inhabited, in this case by checking that there are no duplicate labels via the helper function  $uniqmap :: List[Lbl \times Ty] \rightarrow 1$ , raising

$$\begin{array}{ll} \text{(k-syn)} & \text{(k-syn)} \\ \underline{n' < n} & \Delta \; \Gamma \vdash_{\Phi}^n \sigma :: \mathsf{Ty} & \underline{n' < n} \\ \overline{\Delta \; \Gamma \vdash_{\Phi}^n \mathsf{ana}[n'](\sigma) :: \mathsf{ITm}} & \overline{\Delta \; \Gamma \vdash_{\Phi}^n \mathsf{syn}[n'] :: \mathsf{Ty} \times \mathsf{ITm}} \end{array}$$

Figure 16: Kinding for the SL-EL interface.

an error if there are (we briefly discuss alternative strategies in the supplement). The rest of the definition folds over the three lists provided as input: the list mapping row labels to types provided as the type index, the list of labels provided as the term index, and the list of argument interfaces, which give access to the corresponding row values. We assume a straightforward helper function, *fold3*, that raises an error if the three lists are not of the same length. The base case is the translational empty product.

The recursive case checks, for each row, that the label provided in the term index matches the label in the type index using helper function  $\mathit{lbleq} :: \mathsf{Lbl} \to \mathsf{Lbl} \to 1$ . Then, we request type analysis of the corresponding argument,  $\mathit{rowarg}$ , against the type in the type index,  $\mathit{rowty}$ , by writing  $\mathit{ana}\ \mathit{rowarg}\ \mathit{rowty}$ . Here,  $\mathit{ana}$  is a helper function defined in Sec. 4.3.2 below that triggers type analysis of the provided argument. If this succeeds, it evaluates to a translational internal term of the form  $\rhd(\mathsf{anatrans}[n](\sigma))$ , where n is the position of  $\mathit{rowarg}$  in  $\mathit{args}$  and  $\sigma$  is the value of  $\mathit{rowty}$ . If analysis fails, it raises an error. The final line constructs a nested tuple based on the row value's translation and the recursive result. Taken together, the translational internal term that will be generated for our example involving  $e_{paper}$  above is  $\hat{\iota}_{paper} := (\mathtt{anatrans}[0](\sigma_{title}), (\mathtt{anatrans}[1](\sigma_{conf}), ()))$ , i.e. it simply recalls that the two arguments were analyzed against  $\sigma_{title}$  and  $\sigma_{conf}$ , without yet inserting their translations directly. This will be done after  $\mathit{translation}\ \mathit{validation}$ , triggered by the final premise of (ana-intro) and described in Sec. 4.3.3.

### 4.3.2 Argument Interfaces

The kind of argument interfaces is  $Arg := (Ty \to ITm) \times (1 \to Ty \times ITm)$ , i.e. a product of functions, one for analysis and the other for synthesis. The helpers ana and syn only project them out, e.g.  $ana := \lambda arg :: Arg. fst(arg)$ . To actually perform analysis or synthesis, we must provide a link between the dynamics of the static language and the EL's typing rules. This is purpose of the static forms  $ana[n](\sigma)$  and syn[n]. When consider an argument list of length n, written  $|\overline{e}| = n$ , the opcon definition will receive a static list of length n where the jth entry is the argument interface  $(\lambda ty :: Ty.ana[j](ty), \lambda :: 1.syn[j])$ . This argument interface list is generated by the judgement  $args(n) = \sigma_{args}$ .

The index n on the kinding judgement is an upper bound on the argument index of terms of the form  $\operatorname{ana}[n](\sigma)$  and  $\operatorname{syn}[n]$ , enforced in Figure 16. Thus, if  $\operatorname{args}(n) = \sigma_{\operatorname{args}}$  then  $\emptyset$   $\emptyset$   $\vdash_{\Phi}^n \sigma_{\operatorname{args}} :: \operatorname{List}[\operatorname{Arg}]$ . The rule (ocstruct-intro) ruled out writing either of these forms explicitly in an opcon definition by checking against bound n=0. This is to prevent out-of-bounds errors: tycon providers can only access these forms via the argument interface list, which has the correct length.

The static dynamics of  $\operatorname{ana}[n](\sigma)$  are interesting. After normalizing  $\sigma$ , the argument environment, which contains the arguments themselves and the typing and tycon contexts,  $\mathcal{A} := \overline{e}; \Upsilon; \Phi$ , is consulted to analyze the nth argument against  $\sigma$ . If this succeeds,  $\triangleright(\operatorname{anatrans}[n](\sigma))$  is generated:

$$\frac{\sigma \ \mathrm{val}_{\overline{e};\Upsilon;\Phi} \quad \mathrm{nth}[n](\overline{e}) = e \qquad \Upsilon \vdash_{\Phi} e \Leftarrow \sigma \leadsto \iota}{\mathrm{ana}[n](\sigma) \mapsto_{\overline{e};\Upsilon;\Phi} \rhd (\mathrm{anatrans}[n](\sigma))}$$

If it fails, an error is raised:

$$\frac{\sigma \ \mathrm{val}_{\overline{e};\Upsilon;\Phi} \quad \ \ \, \mathrm{nth}[n](\overline{e}) = e \quad \ \left[\Upsilon \vdash_{\Phi} e \not \Leftarrow \sigma\right]}{\mathrm{ana}[n](\sigma) \ \mathrm{err}_{\overline{e};\Upsilon;\Phi}}$$

$$\begin{array}{c} \vdash^{c}_{\mathcal{A}} \hat{\iota} : \sigma \leadsto \iota^{+} \\ \\ \text{(validate-tr)} \\ \\ \underline{\hat{\iota} \parallel \mathcal{D} \emptyset \hookrightarrow^{c}_{\overline{e};\Upsilon;\Phi} \iota_{abs} \parallel \mathcal{D}' \mathcal{G}} \\ \\ \underline{\hat{\iota} \parallel \mathcal{D} \emptyset \hookrightarrow^{c}_{\overline{e};\Upsilon;\Phi} \iota_{abs} \parallel \mathcal{D}' \mathcal{G}} \\ \\ \underline{\hat{\nu}' \leadsto \delta : \Delta_{abs}} \quad \mathcal{G} \leadsto \gamma : \Gamma_{abs} \\ \\ \underline{\vdash^{c}_{\overline{e};\Upsilon;\Phi} \hat{\iota} : \sigma \leadsto [\delta][\gamma] \iota_{abs}} \end{array}$$

Figure 17: Translation Validation

We write  $[\Upsilon \vdash_{\Phi} e \not= \sigma]$  to indicate that e fails to analyze against  $\sigma$ . We do not define this inductively, so we also allow that this premise be omitted, leaving a non-deterministic semantics nevertheless sufficient for our metatheory.

The dynamics for syn[n] are analogous, evaluating to a pair  $(\sigma, \triangleright(syntrans[n]))$  where  $\sigma$  is the synthesized type.

The kinding rules also prevent these translational forms from being well-kinded when n = 0 and, like trans( $\sigma$ ) in Sec. 4.2.4, they are retained in values of kind ITm.

### 4.3.3 Translation Validation

The judgement  $\vdash_{\mathcal{A}}^{c} \hat{\iota} : \sigma \leadsto \iota^{+}$ , defined by a single rule in Figure 17 and appearing as the final premise of (ana-intro) and the other rules described below, is pronounced "translational internal term  $\hat{\iota}$  generated by an opcon associated with tycon c under argument environment  $\mathcal{A}$  for an operation with type  $\sigma$  is valid, so translation  $\iota$  is produced". For example,

$$\vdash^{\texttt{LPROD}}_{(title; \texttt{"EXMPL 2015"}); \Upsilon_{\texttt{ex}}; \Phi_{\texttt{rstr}} \Phi_{\texttt{lprod}}} \hat{\iota}_{\texttt{paper}} : \sigma_{\texttt{paper}} \leadsto \iota_{\texttt{paper}}$$

The purpose of translation validation is to check that the generated translation will be well-typed *no matter what the translations of types other than those constructed by c are.* 

The first premise generates the selectively abstracted type translation for  $\sigma$  given that c was the delegated tycon as described in Sec. 4.2.5. In our running example, this is  $\tau_{\text{paper/abs}}$ , i.e.  $\alpha_0 \times (\alpha_1 \times 1)$ .

The judgement  $\hat{\iota} \parallel \mathcal{D} \mathcal{G} \hookrightarrow_{\mathcal{A}}^{c} \iota^{+} \parallel \mathcal{D}^{+} \mathcal{G}^{+}$ , appearing as the next premise, relates a translational internal term  $\hat{\iota}$  to an internal term  $\iota$  called a *selectively abstracted term translation*, because all references to the translation of an argument (having any type) are replaced with a corresponding variable, x, which will be of the selectively abstracted type translation of the type of that argument. For our example,  $\hat{\iota}_{paper} \parallel \mathcal{D}_{paper/abs} \emptyset \hookrightarrow_{(title;"EXMPL 2015");\Upsilon_{ex};\Phi_{rstr}\Phi_{lprod}} \iota_{paper/abs} \parallel \mathcal{D}_{paper/abs} \mathcal{G}_{paper/abs}$  where  $\iota_{paper/abs} := (x_0, (x_1, ()))$ .

The type translation store,  $\mathcal{D}$ , discussed previously, and term translation store,  $\mathcal{G}$ , track these correspondences. Term translation stores have syntax  $\mathcal{G} ::= \emptyset \mid \mathcal{G}, n : \sigma \leadsto \iota/x : \tau$ . Each entry can be read "argument n having type  $\sigma$  and translation  $\iota$  appears as variable x with type  $\tau$ ". In the example above,  $\mathcal{G}_{\text{paper/abs}} := 0 : \sigma_{\text{title}} \leadsto title/x_0 : \alpha_0, 1 : \sigma_{\text{conf}} \leadsto$  "EXMPL 2015" $_{\text{IL}}/x_1 : \alpha_1$ .

To derive this, the judgement proceeded recursively along shared forms, as in Sec. 4.2.5. The interesting rule for argument translations derived via analysis is below (syntrans[n] is analogous; see supplement):

The third premise of (validate-tr) generates the type substitution and type formation contexts implied by the final type translation store as described in Sec. 4.2.5. Similarly, each term translation store  $\mathcal G$  implies an internal term substitution,  $\gamma:=\emptyset\mid\gamma,\iota/x$ , and

corresponding  $\Gamma$  by the judgement  $\mathcal{G} \leadsto \gamma: \Gamma$ , appearing as the fourth premise. Here,  $\gamma_{\mathrm{paper/abs}} := title/x_0$ , "EXMPL 2015" $_{\mathrm{IL}}/x_1$  and  $\Gamma_{\mathrm{paper/abs}} := x_0: \alpha_0, x_1: \alpha_1$ .

The critical fifth premise checks the selectively abstracted term translation  $\iota_{paper/abs}$  against the selectively abstracted type translation  $\tau_{paper/abs}$  under these contexts via the internal statics. Here,  $\Delta_{paper/abs}$   $\Gamma_{paper/abs} \vdash \iota_{paper/abs}$  :  $\tau_{paper/abs}$ , i.e.:

$$(\alpha_0, \alpha_1) (x_0 : \alpha_0, x_1 : \alpha_1) \vdash (x_0, (x_1, ())) : \alpha_0 \times (\alpha_1 \times 1)$$

In summary, the translation of the labeled product  $e_{\rm paper}$  generated by LPROD is checked with the references to term and type translations of regular strings replaced by variables and type variables, respectively. But because the definition treated arguments parametrically, the check succeeds.

Applying the substitutions  $\gamma_{\text{paper/abs}}$  and  $\delta_{\text{paper/abs}}$  in the conclusion of the rule, we arrive at the actual term translation  $\iota_{\text{paper}} := (title, (\text{"EXMPL 2015"}_{\text{IL}}, ()))$ . Note that  $\iota_{\text{paper}}$  has type  $\tau_{\text{paper}}$  under the translation of  $\Upsilon_{\text{ex}}$ , i.e.  $\vdash \Upsilon_{\text{ex}}$  ctx  $\leadsto \Gamma_{\text{ex}}$  where  $\Gamma_{\text{ex}} := title$ : str. This relationship will always hold, and implies type safety (Sec. 4.4).

Had we attempted to "smuggle out" a value of regular string type that violated the regular string invariant, e.g. generating  $\hat{\iota}_{bad} := ("", ("", ()), \text{ it would fail, because even though } (""_{IL}, (""_{IL}, ()) : \text{str} \times \text{str} \times 1, \text{ it is not the case that } (""_{IL}, (""_{IL}, ()) : \alpha_0 \times (\alpha_1 \times 1).$  We call this property *translation independence*.

### 4.3.4 Generalized Targeted Operations

All non-introductory operations go through the form for *targeted operations*,  $targop[\mathbf{op}; \sigma_{tmidx}](e_{targ}; \overline{e})$ , where  $\mathbf{op}$  is the opcon name,  $\sigma_{tmidx}$  is the term index,  $e_{targ}$  is the *target argument* and  $\overline{e}$  are the remaining arguments. Concrete desugarings for this form include  $e_{targ}.\mathbf{op}\langle\sigma_{tmidx}\rangle(\overline{e})$  (and variants where the term index or arguments are omitted), projection syntax for use by record-like types,  $e_{targ}$ #lbl, which desugars to  $targop[\#; 1b1](e_{targ}; \cdot)$ , and  $e_{targ} \cdot e_{arg}$ , which desugars to  $targop[\mathbf{conc}; ()](e_{targ}; e_{arg})$ . We show other desugarings, e.g. case analysis, in the supplement.

Whereas introductory operations were analytic, targeted operations are synthetic in @ $\lambda$ . The type and translation are determined by the tycon of the type synthesized by the target argument. The rule (syn-targ) is otherwise similar to (ana-intro) in its structure. The first premise synthesizes a type,  $TC\langle\sigma_{tyidx}\rangle$ , for the target argument. The second premise extracts the tycon definition for TC from the tycon context. The third extracts the *operator index kind* from its opcon signature, and the fourth checks the term index against it.

Figure 10 showed portions of the opcon signatures of RSTR and LPROD. The opcons associated with RSTR are taken directly from Fulton et al.'s specification of regular string types [15], with the exception of **case**, which generalizes case analysis as defined there to arbitrary string patterns, based on the form of desugaring we show in the supplement. The opcons associated with LPROD are also straightforward: # projects out the row with the provided label and **conc** concatenates two labeled products (updating common rows with the value from the right argument). Note that both RSTR and LPROD can define concatenation.

The fifth premise of (syn-targ) extracts the *targeted opcon definition* of **op** from the opcon structure,  $\omega$ . Like the intro opcon definition, this is a static function that generates a translational internal term on the basis of the target tycon's type index, the term index and an argument interface list. Targeted opcon definitions additionally synthesize a type. The rule (ocstruct-targ) in Figure 13 ensures that it is well-kinded. For example, the definition of RSTR's **conc** opcon is shown in Figure 18 (others will be in the supplement).

The helper function *arity2* checks that two arguments, including the target argument, were provided. We then request synthesis of both arguments. We can ignore the type synthesized by the first because by definition it is a regular string type with type index *tyidx*. We case analyze the second against RSTR, to extract its index regular expression (raising an error if it is not of regular string type). We then synthesize the resulting regular

```
\begin{aligned} & \mathsf{syn} \ \mathbf{conc} = \lambda t y i dx :: \mathsf{Rx.} \lambda t m i dx :: 1. \lambda a r g s :: \mathsf{List}[\mathsf{Arg}]. \\ & \mathsf{letpair} \ (a r g 1, a r g 2) = a r i t y 2 \ a r g s \ \mathsf{in} \\ & \mathsf{letpair} \ (\_, t r 1) = s y n \ a r g 1 \ \mathsf{in} \\ & \mathsf{letpair} \ (t y 2, t r 2) = s y n \ a r g 2 \\ & \mathsf{tycase}[\mathsf{RSTR}] \ (t y 2; t y i d x 2. \\ & (\mathsf{RSTR} \langle rx concat \ t y i dx \ t y i dx 2 \rangle, \, \triangleright (s concat \ \lhd (t r 1) \ \lhd (t r 2))) \\ & \mathsf{;} \ \mathsf{raise}[\mathsf{Ty} \times \mathsf{ITm}]) \end{aligned}
```

Figure 18: A targeted opcon definition,  $\sigma_{\rm rstr/conc}$ .

string type, using the helper function *rxconcat* ::  $Rx \to Rx \to Rx$  which generates the synthesized type's index by concatenating the indices of the argument's types consistent with the specification in [15]. Finally the translation is generated using helper function sconcat:  $str \to str \to str$ , the translational term for which we assume has been substituted in directly.

The last premise of (syn-targ) again performs translation validation as described above. The only difference relative to (ana-intro) is that that we check the term translation against the synthesized type but the delegated tycon is that of the type synthesized by the target argument.

### 4.3.5 Operations Over Other Types

The rules (ana-intro-other) and (syn-targ-other) are used to introduce and simulate targeted operations on terms of all types constructed by any "other" tycon. In both cases, the term index, rather than the tycon context, directly specifies the translational internal term to be used.

### 4.4 Metatheory

We will now state the key metatheoretic properties of  $@\lambda$ . The proofs are in the supplement.

**Kind Safety** Kind safety ensures that normalization of well-kinded static terms cannot go wrong. We can take a standard progress and preservation based approach.

```
Theorem 1 (Static Progress). If \emptyset \emptyset \vdash_{\Phi}^{n} \sigma :: \kappa \text{ and } |\overline{e}| = n \text{ then } \sigma \mapsto_{\overline{e};\Upsilon;\Phi} \sigma' \text{ or } \sigma \text{ val}_{\overline{e};\Upsilon;\Phi} \text{ or } \sigma \text{ err}_{\overline{e};\Upsilon;\Phi}.
```

```
Theorem 2 (Static Preservation). If \emptyset \emptyset \vdash_{\Phi}^{n} \sigma :: \kappa \text{ and } \vdash \Phi \text{ and } \vdash_{\Phi} \Upsilon \text{ ctx } \leadsto \Gamma \text{ and } \sigma \mapsto_{\overline{e};\Upsilon;\Phi} \sigma' \text{ then } \emptyset \emptyset \vdash_{\Phi}^{n} \sigma' :: \kappa.
```

The case in the proof of Theorem 2 for  $\sigma = \text{syn}[n]$  requires that the following theorem be mutually defined.

```
Theorem 3 (Type Synthesis). If \vdash \Phi and \vdash_{\Phi} \Upsilon ctx \leadsto \Gamma and \Upsilon \vdash_{\Phi} e \Rightarrow \sigma \leadsto \iota then \sigma type_{\Phi}.
```

**Type Safety** Type safety in a typed translation semantics requires that well-typed external terms translate to well-typed internal terms. Type safety for the IL [16] then implies that evaluation cannot go wrong. To prove this, we must in fact prove a stronger theorem: that a term's translation has its type's translation under the typing context's translation (the analagous notion is *type-preserving compilation* in type-directed compilers [33]):

```
Theorem 4 (Type-Preserving Translation). If \vdash \Phi and \vdash_{\Phi} \Upsilon ctx \leadsto \Gamma and \vdash_{\Phi} \sigma type \leadsto \tau and \Upsilon \vdash_{\Phi} e \Leftarrow \sigma \leadsto \iota then \emptyset \vdash \Gamma and \emptyset \vdash \tau and \emptyset \vdash \Gamma \vdash \iota : \tau.
```

*Proof Sketch.* The interesting cases are (ana-intro), (ana-intro-other), (syn-trans) and (syn-trans-other); the latter two arise via subsumption. The result follows directly from the

translation validation process, combined with lemmas that state that all variables in  $\Delta_{\rm abs}$  and  $\Gamma_{\rm abs}$  in (tr-validate) have well-formed/well-typed substitutions in  $\delta$  and  $\gamma$ , so applying in the conclusion them gives a well-typed term.

**Hygienic Translation** Note above that the domains of  $\Upsilon$  (and thus  $\Gamma$ ) and  $\Gamma_{abs}$  are disjoint. This serves to ensure *hygienic translation* – translations cannot refer to variables in the surrounding scope directly, so uniformly renaming a variable cannot change the meaning of a program. Variables in  $\Upsilon$  can occur in arguments (e.g. title in the earlier example), but the translations of the arguments only appear *after* the substitution  $\gamma$  has been applied. We assume that substitution is capture-avoiding in the usual manner.

**Conservativity** Extending the tycon context also conserves all *tycon invariants* maintained in the original tycon context. An example of a tycon invariant is the following:

**Tycon Invariant 1** (Regular String Soundness). *If*  $\emptyset \vdash_{\Phi_{rstr}} e \Leftarrow RSTR \langle /r/ \rangle \leadsto \iota$  *and*  $\iota \Downarrow \iota'$  *then*  $\iota' = "s"$  *and* "s" *is in the regular language*  $\mathcal{L}(\mathbf{r})$ .

*Proof Sketch.* We have fixed the tycon context  $\Phi_{rstr}$ , so we can essentially treat the calculus like a type-directed compiler for a calculus with only two tycons,  $\rightharpoonup$  and RSTR, plus some "other" one. Such a calculus and compiler specification was given in [15], so we must simply show that the opcon definitions in RSTR adequately satisfy these specification using standard techniques for the SL, a simply-typed functional language [10]. The only "twist" is that the rule (syn-targ-other) can synthesize a regular string type paired with any translational term  $\hat{\tau}$ . But it will be validated against  $\tau_{abs} = \alpha$  because rule (abs-ext-not-delegated-new) applies in that case. Thus, the invariants cannot be violated by direct application of parametricity in the IL (i.e. this case can always be dispatched via a "free theorem") [35].

Another way to interpret this argument is that "other" types simulate all types that might arise from "the future" in that they can have any valid type translation (given directly in the type index) and their operators can produce any valid term translation (given directly in the term index). Because they are distinct from all "present" tycons, our translation validation procedure ensures that they can be reasoned about uniformly – they cannot possibly violate present invariants because they do not even know what type of term they need to generate. The only way to generate a term of type  $\alpha$  is via an argument, which inductively obeys all tycon invariants.

**Theorem 5** (Conservativity). *If*  $\vdash \Phi$  *and*  $TC \in dom(\Phi)$  *and a tycon invariant for* TC *holds under*  $\Phi$ .

• For all  $\Upsilon, e, \sigma_{tyidx}$ , if  $\Upsilon \vdash_{\Phi} e \Leftarrow TC\langle \sigma_{tyidx} \rangle \leadsto \iota$  and  $\vdash_{\Phi} \Upsilon \mathsf{ctx} \leadsto \Gamma$  and  $\vdash_{\Phi} TC\langle \sigma_{tyidx} \rangle \leadsto \tau$  then  $P(\Gamma, \sigma_{tyidx}, \iota)$ .

then for all  $\Phi' = \Phi$ , tycon TC'  $\{\theta'\} \sim \mathsf{tcsig}[\kappa'] \{\chi'\}$  such that  $\vdash \Phi'$ , the same tycon invariant holds under  $\Phi'$ :

• For all  $\Upsilon, e, \sigma_{tyidx}$ , if  $\Upsilon \vdash_{\Phi'} e \Leftarrow TC\langle \sigma_{tyidx} \rangle \leadsto \iota$  and  $\vdash_{\Phi'} \Upsilon \leadsto \Gamma$  and  $\vdash_{\Phi'} TC\langle \sigma_{tyidx} \rangle \leadsto \tau$  then  $P(\Gamma, \sigma_{tyidx}, \iota)$ .

(if proposition  $P(\Gamma, \sigma, \iota)$  is modular, defined below)

*Proof Sketch.* Our proof of the more general property is a realization of this intuition that "other" types simulate future types. We simply map every well-typed term under  $\Phi$  to a well-typed term under  $\Phi$  with the same translation, and if the term has a type constructed by a tycon in  $\Phi$ , e.g. TC, the new term has a type constructed by that tycon with the same type translation, and only a slightly different type index. In particular, the mapping's effect on static terms is to replace all types constructed by TC' with a type constructed by

other  $[m;\kappa'_{\rm tyidx}]$ . If  $P(\Gamma,\sigma_{\rm tyidx},\iota)$  is preserved under this transformation on  $\sigma_{\rm tyidx}$  then we can simply invoke the existing proof of the tycon invariant. We call such propositions modular. Non-modular propositions are uninteresting because they distinguish tycons "from the future". Our regular string proposition is clearly modular because regular expressions don't contain types at all.

On external terms, the mapping replaces all intro and targeted terms that delegated to TC' with equivalent ones that pass through rules (ana-intro-other) and (syn-targ-other) by pre-applying the intro and targeted opcon definitions to generate the term indices.

### 4.5 Timeline

Contribution 4.1 is in submission to PLDI 2015. The supplemental material (approximately 70 pages) contains the majority of the details, although a bit more needs to be done to flesh out the proofs at the end. This will be done in Spring 2015.

### 5 Extensible Editor Services

Figure 19: (a) An example code completion palette associated with the Color class. (b) The elaboration generated by this palette.

Software developers today make heavy use of the code completion feature commonly found in contemporary source code editors [22]. Code completion typically takes the form of a floating menu containing contextually-relevant variables, assignables, fields, methods, types and other code snippets. When an item in this menu is selected, code is inserted immediately, without further input from the developer. By navigating and selecting from this menu, developers are able to avoid many common spelling and logic errors, eliminate unnecessary keystrokes and explore unfamiliar APIs without incurring the mental overhead associated with switching to an external documentation tool.

Contemporary code completion systems are difficult to extend because a fixed strategy determines the completions that are available. Library providers cannot directly specify specialized code generation logic or provide interactive forms of assistance.

**Contribution 5.1** (Active Code Completion). We introduce a technique called *active code completion* that makes developing and integrating a broad array of tycon-specific code generation tools directly into an editor, via the familiar code completion command, significantly simpler.

We discuss active code completion in the context of object construction in Java rather than Wyvern or ML because 1) type-aware editors for Java are better developed than those for other languages; 2) we wish to do empirical studies; and (3) because Java already provides a way to associate metadata with classes. The techniques in this section apply equally well to type-aware editors for any system with a similar set of basic mechanisms.

For example, consider the following Java code fragment:

```
public Color getDefaultColor() {
    return _
```

If the developer invokes the code completion command at the indicated cursor position (\_), the editor looks for a *palette definition* associated with the *type* that the expression being entered is being analyzed against, which in this case is Color (due to the return type annotation on the method). If an associated palette is found, a menu item briefly describing this palette is added to the standard code completion menu. When selected, the corresponding palette is shown, replacing the standard code completion menu. Figure 19(a) gives an example of a simple palette that may be associated with the Color class<sup>4</sup>.

The developer can interact with such palettes to provide parameters and other information related to their intent, and receive immediate feedback about the effect these choices will have on the behavior of the value being constructed. When this interaction is complete, the palette produces an elaboration for insertion at the cursor, of the type (here, class) that the palette was associated with (Figure 19(b)).

<sup>&</sup>lt;sup>4</sup>A video demonstrating this process is available at http://www.cs.cmu.edu/~NatProg/graphite.html.

This is, in essence, an edit-time variant of the mechanism used in Wyvern to support type-specific syntax. As in Sec. 3, we associate a palette with a declared tycon by providing metadata, here in the form of a class annotation. For example, we might write:

```
1     @GraphitePalette(url="http://cs.cmu.edu/~comar/color-palette.html")
2     class Color { ... }
```

Were a type-aware editor for Wyvern written, it might instead use metadata:

```
objtype Color

metadata : HasPalette = new
val palette_url = <http://cs.cmu.edu/~comar/color-palette.html>
```

**Contribution 5.2** (Preliminary Developer Survey). We sought to address the following questions before designing and implementing our active code completion system:

- What *specific* use cases exist for this form of active code completion in a professional development setting?
- What *general* criteria are common to types that would and would not benefit from an associated palette?
- What are some relevant usability and design criteria for palettes designed to address such use cases?
- What capabilities must the underlying active code completion system provide to enable these use cases and user interface designs?

To help us answer these design questions, we conducted a survey of 473 professional developers. Their responses, along with information gathered from informal interviews and code corpus analyses, revealed a number of non-trivial functional requirements for palette interfaces as well as the underlying active code completion architecture. The primary concerns relevant to this thesis are:

- The palette mechanism should not be tied to a specific editor implementation.
- The palette mechanism should not be able to arbitrarily access the surrounding source code.
- We provide a mechanism by which users can associate palettes with types externally. This could cause conflicts with palettes that the type defines itself.

Participants also suggested a large number of use cases, demonstrating the broad applicability of this technique. We organized these into several broad categories.

**Contribution 5.3** (Design and Implementation of Graphite). Next, we developed Graphite, an Eclipse plug-in that implements the active code completion architecture for the Java programming language, allowing Java library developers to associate custom palettes with their own classes. We describe several design choices that we made to satisfy the requirements discovered in our preliminary investigations and examine trade-offs.

**Contribution 5.4** (Graphite Pilot Study). Finally, we conducted a pilot lab study with a more complex palette, implemented using Graphite, that assists developers as they write regular expressions. The study provides specific evidence in support of the broader claim that highly-specialized tools that are integrated directly with the editing environment are useful. We conclude that active code completion systems like Graphite are useful because they make developing, deploying and discovering such tools fundamentally simpler.

### 5.1 Timeline

This work has been published at ICSE 2012 [27] and we do not anticipate further work.
